INTRODUCTION

The best strategy to handle blood vessels during a neurosurgical procedure, either purely neurovascular or even neuro-oncological, is sometimes still a matter of debate and often a univocal approach does not exist.

For instance, one of the main issues in brain vessels management concerns planned venous sacrifice, which can lead to devastating consequences but, at the same time, under certain circumstances, it may actually be desirable to enlarge surgical exposure of the target site or to increase the extent of resection in brain tumor surgery (Broggi et al. 2016; Jang et al. 2012; Kiya et al. 2001; Liebelt et al. 2017; Masuoka et al. 2009; Mathiesen et al. 2014; McNatt et al. 2011; Nakase et al. 2005; Schaller and Graf 2004; Sindou, Auque, and Jouanneau 2005; Sughrue et al. 2011; Suzuki et al. 2003). Furthermore, during neuro-oncological procedures, an unexpected arterial damage can occur: in this dramatic event, neurosurgeons would benefit from a fast real-time tool able to identify regions of parenchymal hypoperfusion in order to predict the effects of this inadvertent occlusion and, if

possible, to reverse the situation (Acerbi, Cavallo, and Ferroli 2016; Kamp et al. 2012; Takagi et al. 2007; Ye et al. 2013; Ng et al. 2013; Kobayashi et al. 2014; Uchino et al. 2014).

Microscope-integrated indocyanine green video-angiography (ICG-VA) has been employed in the last decades in vascular neurosurgery to better visualize cerebral vessels during aneurysm clipping, bypass surgery or arteriovenous malformation resection (Hettige and Walsh 2010; Dashti et al. 2009; Ferroli et al. 2010; Ferroli, Acerbi, Tringali, et al. 2011; Ferroli, Nakaji, et al. 2011; Ferroli et al. 2008; Hao et al. 2013; De Oliveira et al. 2008; Hide et al. 2015; Imizu et al. 2008; Li et al. 2009; Raabe et al. 2003; Raabe, Beck, and Seifert 2005; Raabe et al. 2009). But, ICG-VA is also a useful adjunct in almost any kind of neurosurgical procedure, since it allows to study venous flow dynamics intraoperatively, both in pathological (Raabe et al. 2003; Schebesch et al. 2015) and in normal vessels (Takagi et al. 2012), and to predict the consequences of venous sacrifice during different surgical procedures (Uchino et al. 2014).

In 2011, our group was the first to propose that ICG-VA be used regularly to evaluate vascular anatomy in central nervous system (CNS) tumors and its role in shaping the surgical strategy (Ferroli, Acerbi, Tringali, et al. 2011): in particular, we analyzed venous flow dynamics, taking into account flow velocity, flow direction and uniform/nonuniform filling, and we proposed a classification with the aim of predicting the effects of venous sacrifice. Since then, very few reports on the application of ICG-VA in the context of CNS tumors resection have been published (D'Avella et al. 2013; Endo et al. 2013; Hojo et al. 2014; Hwang et al. 2010; Kamp et al. 2012; Takami et al. 2017; Takeshima et al. 2015).

Lately, the integration of the new FLOW 800 software (*FLOW 800 Software Analysis Tool, Pentero and Kinevo microscopes, Carl Zeiss Co., Oberkochen, Germany*) in the operating microscope, has allowed to perform, with the data derived from the standard ICG-VA, a post-processing semi-quantitative analysis of blood flow in the arteries, brain parenchyma (capillary phase) and veins, thus expanding our knowledge on the pathophysiology of the different vascular phases in neurosurgical procedures (Acerbi, Cavallo, and Ferroli 2016).

In this chapter, the authors present their extensive experience with ICG-VA and FLOW 800 analysis in a decennial retrospective series of patients undergoing surgical removal of cerebral and spinal tumors.

METHODS

Patients

In the period between January 2009 and December 2018, 2173 patients underwent surgical removal of a CNS tumor at the Department of Neurosurgery of the Fondazione IRCCS Istituto Neurologico Carlo Besta, Milano (Italy). All patients affected by CNS neoplasms and scheduled for surgical removal, gave their informed consent to the utilization of ICG-VA. In 204 out of 2173 (9.4%) cases, ICG-VA and FLOW 800 analysis were used at least once during surgical resection; all surgical videos and images were reviewed with the aim of categorizing the different specific applications of this technique. All data were obtained from an institutional, prospectively collected database, containing all patients'

demographic data, type of pathology, surgical management and clinical outcome. The present study has been approved by the Istituto Neurologico Carlo Besta Ethical Committee.

Surgical Management

All patients underwent standard preoperative evaluation including blood tests, general and neurological clinical assessment and preoperative MRI, including standard volumetric sequences (T1-weighted with intravenous contrast administration and T2-weighted) for brain and spinal tumors. The surgical approach was tailored to each individual patient according to the location and features of the tumor itself. All the patients were operated with the best available tools at the moment of the surgery, such as neuronavigation, fluorescent-guided techniques, contrast-enhanced ultrasound, neurophysiological and clinical monitoring according to the surgeon's preference. Tumors were histologically classified based on the 2007 WHO CNS tumors classification (Louis et al. 2007) before May 2016, and on the current WHO 2016 revision, after May 2016 (Louis et al. 2016).

Figure 1. Example of ICG-VA and FLOW 800 analysis in a case of left temporal adenocarcinoma metastasis (A: T1-weighted axial with i.v. contrast administration pre-operative MRI). Under standard white-light microscopy view (B), the superficial projection of the tumor is identified by neuronavigation, as depicted by the asterisk; the same superficial region is explored under YELLOW 560 filter (C), specific for SF, to highlight the superficial component of the tumor as bright yellow-green. The FLOW 800 algorithm is able to reconstruct the map of delay time (D) based on the time to half-maximal fluorescence in the area exposed by the craniotomy and the map of fluorescence intensity (E) based on intensity detected by the camera and graded by the average AIs. In the map of delay time, arteries are represented in red, veins in blue, and the arterialized portion of the veins in green/yellow (arrow). The software also makes it possible to study different ROIs in the map of gray intensity, with automatic reconstruction of flow curves over time, as depicted in F. In the graph of this case, the arterial curve is shown in red; the venous curve in blue; and the arterIALIZED part of the vein, with faster flow than normal veins, in green.

ICG Video-Angiography with FLOW 800 Analysis

The ICG-VA technique has already been extensively described (Ferroli, Nakaji, et al. 2011; Ferroli, Acerbi, Tringali, et al. 2011; Acerbi, Vetrano, Sattin, de Laurentis, et al. 2018; Acerbi, Vetrano, Sattin, Falco, et al. 2018); briefly, intravenous ICG administration with a standard dose of 12.5 mg in single bolus, was administered every time, upon surgeon's request, never exceeding the maximum daily dose of 5 mg/kg (Hope-Ross et al. 1994). Flow analysis was performed by means of the FLOW 800 software, integrated in the surgical microscope. The algorithm calculated fluorescence intensities in the exposed areas based on arbitrary intensity units (AIs) detected by the camera and it reconstructed maps of maximal fluorescence intensities and of delay times (time interval until 50% of maximum fluorescence). Specifically, the maps were showed as grey-scale of maximal fluorescence intensities, and as color-scale based on the time to half-maximal fluorescence, respectively. In addition, the course of fluorescence could be further analyzed in any area of the exposed brain, including parenchyma, by using freely definable regions of interest (ROIs) (Figure 1).

RESULTS

Patients and CNS Tumors

In the 204 cases included, there were 183 intracranial (51 meningiomas, 36 high-grade gliomas, 28 hemangioblastomas, 19 cerebral metastases, 7 chordomas, 5 tumors of the pineal region and 37 other neoplasms) and 21 spinal tumors (10 ependymomas, 5 hemangioblastomas, 3 pilocytic astrocytomas, 2 astrocytomas [WHO II] and 1 schwannoma). Additionally, in 126 cases, sodium fluorescein was used to better visualize and remove intra-axial tumors enhancing after contrast medium injection on the preoperative MRI: tumors were visualized using a fluorescein-guided technique (YELLOW 560 filter on the same surgical microscope), with the dose of 5 mg/kg, according to the recommendations of the FLUOCERTUM study, approved by our Institutional Ethics Committee in 2016 (Acerbi, Broggi, et al. 2018; Acerbi et al. 2017; Acerbi et al. 2016; Acerbi et al. 2015).

ICG-VA allowed us to optimally visualize arterial, capillary-parenchymal and venous phases of exposed vessels and brain regions, whenever it was considered necessary by the first surgeon. Even in the cases in which fluorescein was used, ICG-VA could provide useful information and depict vascular anatomy; no interactions due to the contemporary use of sodium fluorescein and ICG-VA, making tumor visualization difficult, were registered. In selected cases, ICG injections could be repeated, after a wash-out period of at least 10 minutes. No adverse reactions to ICG injections, even repeated ones, or to the combined use of fluorescein and ICG, were observed. Depending on the pathology, the following 5 main applications of ICG-VA and FLOW 800 in neuro-oncological surgery were employed (Table 1).

Table 1. Field of application and number of ICG-VA procedures, related to number of cases and tumor histological types

EXTRADURAL ANALYSIS BEFORE DURAL OPENING

ICG video-angiography was used extradurally in order to identify the course of bridging cortical veins, before dural opening, in supratentorial lesions, especially for parasagittal meningiomas involving the superior sagittal sinus but also for every kind of tumor in which an interhemispheric approach was deemed necessary (Vetrano, Ferroli, and Acerbi 2018).

ICG-VA showed an advantage also during posterior fossa surgery: in case of brainstem lesions, extradural analysis could prove the feasibility of sigmoid sinus sacrifice (that is, if the presence of retrograde flow could be documented) when performing a petro-occipital trans-sigmoid surgical route to approach deep-seated tumors. Finally, for meningiomas involving the torcular/transverse sinus, ICG-VA showed both the position and the patency of afferent and efferent sinuses before dural opening (Figure 2).

In this field of application, a specific advantage related to the use of FLOW 800 analysis was not found, since all the information could be retrieved with maps of grey intensity as in classic ICG-VA.

Figure 2. Example of extradural analysis in a case of a left parasagittal meningioma (preoperative MRI, axial T1-weighted post i.v. contrast administration in A and coronal T2-weighted in B) involving the superior sagittal sinus (SSS) in which, with the aid of ICG-VA (D), it was possible to identify the sinus and a patent cortical vein (arrow) draining into the SSS, that was not clearly identifiable under white light (C). A case of a right side infra- and supra-tentorial meningioma involving the torcular (preoperative MRI, axial T1-weighted post i.v. contrast administration in E and sagittal T2-weighted in F), approached in semisitting position, in which the extradural examination (white light in G, ICG-VA in H) revealed the patent transverse sinus (TS) below the occipital lobe (OccL) and above the cerebellar parenchyma.

MANAGEMENT OF VENOUS SACRIFICE BY ICG TEMPORARY CLIPPING TEST

ICG temporary clipping test was developed by our group much like a provocative occlusion test for those occasions in which planned venous sacrifice was considered necessary to create/enlarge a surgical corridor and to maximize the extent of resection (Ferroli, Acerbi, Tringali, et al. 2011; Ferroli, Nakaji, et al. 2011).

Briefly, the test was performed as follows: after a baseline ICG videoangiogram was obtained, a temporary clip (or more simply, the closed tips of a bipolar forcep) was placed on the vein to be tested and flow direction and dynamics were again analyzed by ICG videoangiography; flow stagnation was considered to be a sign of lack of collateral circulation whereas flow reversal was interpreted as a sign of the presence of collateral circulation, suggesting compliance to sacrifice.

A positive temporary clipping test, indicating venous sacrifice feasibility, was found to be correlated with a baseline ICG-VA pattern of slow-draining veins (slow and nonuniform filling, with multiple tributaries and one large collector, and a time to half-maximal fluorescence greater than 5 seconds of the arterial phase), whereas fast-draining veins (fast and homogenous filling and a time to half-maximal fluorescence that was within 5 seconds of

the arterial phase) usually exhibited stagnation when clipped, suggesting their non-compliance to sacrifice due to the assumed absence of collateral venous circulation (Figure 3). Although we reported this association, we did not systematically study the effects of venous sacrifice on the basis of ICG-VA assessment of venous flow characteristics; furthermore, an arterovenous 5-second gap mark as a criterion to distinguish the 2 groups was arbitrarily chosen.

Nevertheless, since it is safe and easy to use, an ICG temporary clipping test is performed in every case in which the authors want to examine the effect of venous sacrifice and to determine its tolerability. In particular, the test is routinely performed on different bridging veins, draining to the superior sagittal, sphenoparietal, and superior petrosal sinuses, to the tentorium, and also on posterior median sulcus veins in the spinal cord.

The use of FLOW 800 analysis in association to ICG-VA helps to evaluate venous flow and flow reversal during the temporary clipping, especially in borderline cases.

Figure 3. Example of a clipping test to evaluate the possibility to sacrifice a group of bridging veins to the superior sagittal sinus (SSS) during a right transcallosal approach for removal of an intraventricular lesion (subependymal giant cell astrocytoma). Under microscopic view (A), two main bridging vein complexes draining into the SSS are clearly identified. After intravenous administration of ICG, the FLOW 800 software view shows the temporal fluorescence projection in the exposed vessels under physiological conditions (B). ROIs are identified on a classic ICG-VA map: the red and violet ROIs are positioned on the fast vein, while the green and blue ROIs are on the slow vein (E). The graph clearly confirms the difference in flow speed between a fast vein and a slow vein, both of them with an anterograde flow (F). The clipping test is shown in microscopic view (C). The FLOW 800 software identifies the changes in temporal fluorescence projection in the exposed vessels during the clipping test, demonstrating that the fast vein is now draining through a common chamber into the slow one (D). The same ROIs are positioned as in E, during the clipping test (G). The graph shows that the flow speed in the two veins is now very similar, with an inversion of the flow (retrograde) in the previous slow vein (H). Postoperative MRI, axial T2-weighted (I), coronal FLAIR sequence (L) and coronal T1-weighted (M), excluding ischemia, edema or hemorrhage in the territory drained by the clipped vein complex.

Figure 4. Exemplificative use of ICG-VA during the resection of a right rolandic glioblastoma. A: Preoperative T1-weighted with i.v. contrast administration MRI. B: After dural opening, the standard white-light microscopic view shows the superficial part of the tumor with a pathological vessel (asterisk), and an arterialized red flow (arrow) in the context of a cortical vein draining toward the superior sagittal sinus. C: The classic ICG-VA confirms the point where the fistula and the large cortical vein meet (arrow) and other pathological vessels in the tumoral area. D: The map of delay time after FLOW 800 analysis better depicts the arterIALIZED flow into the vein (in red-yellow), compared to normal venous flow in blue in the more proximal venous compartment; in addition, it clearly identifies the superficial component of the glioblastoma as a red nodule (asterisk). E–H: ICG-VA and FLOW 800 analysis are repeated after tumor removal (F), showing the flow normalization in the cortical vein and normal perfusion in the brain parenchyma close to the surgical cavity, both on the map of gray intensity (G) and on the delay time one (H). In E, a postoperative T1-weighted with i.v. contrast administration MRI scan confirms total tumor resection.

PRE-RESECTION ANALYSIS

ICG-VA was often performed before tumor resection. For parenchymal tumors abutting the brain/spinal cord surface, a superficial vascular analysis was used to demonstrate areas of pathological neo-angiogenesis within the tumor, or the presence of arterovenous fistulas with vein flow disturbances especially in high-grade gliomas or in hemangioblastomas. Moreover, in this specific case, FLOW 800 analysis allowed to better discriminate the margins of the tumor based on maps of delay time and on the analysis of flow curves showing pathological neo-angiogenesis and vessels or the presence of arterovenous fistulae (Figure 4). In the oncological cases undergoing fluorescein-guided removal (high-grade gliomas, metastases and pylocytic astrocytomas) (Cavallo et al. 2018), the neo-angiogenesis areas shown on maps of delay times, corresponded to the areas highlighted by fluorescein (Figure 1C).

In few cases, ICG video-angiography showed brain congestion with a delayed flow, particularly in the parenchymal phase, due to tumor mass effect. The use of FLOW 800 analysis, even if not essential to show this finding, allowed to identify a slower time to peak in post-processing analysis due to cerebral congestion; if repeated post-resection, the same analysis could show a steeper flow curve, indicating an improvement of cortical flow.

ANALYSIS DURING AND AFTER TUMOR RESECTION

ICG-VA and FLOW 800 analysis performed during and after tumor resection currently represent the most frequent indication.

While in the other cases, we predominately addressed the venous system, in this field of application, arterial evaluation was the main focus, especially when an inadvertent injury occurred.

The authors often perform ICG video-angiography to evaluate the patency of arteries directly encased by skull base tumors, such as meningiomas, cranial nerve schwannomas, craniopharyngiomas or chordomas, especially for recurrent lesions. In this context, damage of an artery, likely one of the Willis polygon, is a dramatic situation which the neurosurgeon has to manage within the shortest possible time and with the best available technologies. In case of arterial fissuration, after bleeding stabilization and/or arterial direct repair, ICG video-angiography was routinely performed: standard ICG-VA survey was useful to depict flow disturbances whereas FLOW 800 post hoc analysis resulted fundamental in order to visualize cerebral regions of hypoperfusion and to evaluate the delay time in arterial perfusion. In selected cases, a rescue extracranial-intracranial (superficial temporal artery to middle cerebral artery) end to side bypass was performed to reverse the situation and ICG-VA with FLOW 800 analysis was repeated after the anastomosis showing bypass patency with no ischemic insults in brain cortical areas exposed by the craniotomy.

Regarding subcortical lesions, predominantly gliomas and metastases, in case of arterial injury, ICG-VA and FLOW 800 analysis helped the surgeon to identify brain regions vascularized by the specific damaged branch: in case of an eloquent artery, i.e., vessels that feeds brain eloquent parenchyma, such as the rolandic branch of the middle cerebral artery, a rescue intracranial-intracranial end to side or side to side or end to end bypass, using another cortical branch as donor artery, was executed, in order to revert the hypoperfusion, avoiding postoperative ischemic complications (Acerbi, Cavallo, and Ferroli 2016). Also in this context, ICG-VA with FLOW 800 analysis was repeated after the anastomosis to assess bypass patency (Figure 5).

Within the series, there was also a case of a left temporal glioblastoma with an associated unruptured posterior communicating artery aneurysm. In this case, ICG-VA was used to characterize the aneurysm and to check arterial patency, both posterior communicating and choroidal, after its clipping (Acerbi et al. 2016).

On the other hand, the identification, during tumor removal, of a thrombosed vein encased by the lesion, as detectable by ICG-VA, allowed the surgeon to remove it, preserving the point of reverse flow to a collateral vessel, which is identified with the video-angiographic study (Figure 6).

In several cases, which were also studied with a temporary clipping test or a pre-resection analysis, ICG-VA with FLOW 800 analysis was performed post-tumor resection to directly assess brain or spinal cord perfusion, even when arterial manipulation was not performed during surgical maneuvers. The same ICG video-angiographic study and, more precisely, the use of maps of delay times and flow curve analysis based on FLOW 800 software allowed to evaluate the patency and flow characteristics of the veins manipulated during surgical resection and to assess the effect of unintended or necessary venous sacrifice.

Figure 5. A: Intraoperative image under white-light microscopic magnification of the brain parenchyma during a trans-sulcus approach to reach a temporo-parietal subcortical metastasis (preoperative T1-weighted axial with i.v. contrast administration MRI is shown in E). B: Same area at the end of tumor removal after coagulation and section of the encased middle cerebral artery branch (black arrow). No difference in macroscopic appearance of the brain surface can be highlighted. The subcortical strip electrode toward the rolandic area is shown by a white arrow. C: Color map of delay time of ICG-VA with FLOW 800 software suggests a reduced blood flow in the rolandic area vascularized by the coagulated middle cerebral artery branch. D: Color map of delay time of ICG-VA with FLOW 800 software after intracranial-intracranial bypass shows the revascularization of the rolandic area. Postoperative MRI shows no ischemic region (axial DWI sequence in F) and the patency of the bypass (asterisk in T1-weighted axial with i.v. contrast administration MRI in G).

Figure 6. B: After resection of a left temporal glioblastoma (preoperative T1-weighted axial with i.v. contrast administration MRI in A), the left vein of Labbé is found to be encased by residual neoplastic tissues (asterisk). C: ICG-VA shows that the proximal segment of the vein closer to the transverse sinus is already thrombosed (asterisk), with a collateral circulation that developed in the distal segment of the vein, draining toward the sylvian venous system (black arrow in B, white arrow in C). Therefore, it was possible to sacrifice the vein of Labbé without clinical consequences, achieving a gross total resection.

In cases in which the pre-resection analysis documented the presence of an arterovenous fistula, ICG video-angiography with FLOW 800 analysis was performed postoperatively to evaluate involved veins, usually confirming the normalization of venous flow after tumor removal (Figure 4F-H).

PRE-MYELOTOMY ANALYSIS

ICG-VA was used in selected cases of spinal cord lesions not abutting the spinal cord surface to highlight the posterior median sulcus based on the position of posterior veins exiting the sulcus itself (Figure 7). During pre-myelotomy analysis, the use of FLOW 800 with maps of delay time did not represent a specific advantage.

Figure 7. Intramedullary C2–C6 ependymoma not abutting the spinal cord surface: the spinal cord appears edematous and the median sulcus is not easily recognizable (A). The ICG-VA study (B) highlights a posterior vein (arrows) exiting the median sulcus, improving its identification. The map of delay times is shown in a corresponding image (C).

DISCUSSION

Indocyanine green video-angiography is an intraoperative technique designed to highlight superficial vessels during neurosurgical procedures; the FLOW 800 analysis software (*Carl Zeiss Meditec*) has further expanded the usefulness of ICG-VA, especially in neuro-oncological surgery.

In the last 10 years the authors gained a wide experience with these techniques, applying them to various fields of neurosurgery (Acerbi, Vetrano, Sattin, de Laurentis, et al. 2018; Acerbi, Vetrano, Sattin, Falco, et al. 2018; Ferroli, Acerbi, Tringali, et al. 2011). In particular, from the series here presented, five possible applications of ICG-VA and FLOW 800 during surgical removal of CNS tumors have emerged: a) extradural analysis to explore sinuses patency and bridging veins anatomy before dural opening; b) ICG temporary clipping test to

verify the feasibility of venous sacrifice in deeply located tumors; c) pre-resection analysis to identify pathological vascularization (arterialized veins, neo-angiogenesis and distorted regional venous outflow); d) analysis during and after tumor resection to identify the effects of an unintended/compelled venous sacrifice or of an unintentional arterial damage in real-time and to evaluate vessels patency and parenchymal perfusion after tumor removal; e) pre-myelotomy analysis during intramedullary tumors excision to highlight the posterior median sulcus.

In 2011, our group was the first to propose the use of classic ICG-VA during the resection of CNS tumors, based on a retrospective series of patients treated between 2006–2008 (Ferroli, Acerbi, Tringali, et al. 2011). That study focused mainly on two aspects: the evaluation of pre-resection video-angiography, which provided useful information on the tumoral circulation and the pathology-induced alterations in surrounding brain circulation, and post-resection examination, which allowed for a quick, real-time check of the patency of those vessels that were closely related to the tumor mass and that the surgeon aimed to preserve. However, at that time, the FLOW 800 software was not available yet, while, nowadays, a semiquantitative analysis of blood flow in the brain area exposed by the craniotomy can be performed. In particular, the algorithm integrated in the surgical microscope is able to reconstruct maps of gray intensity based on the average AIs of infrared fluorescence detected by the microscope camera, and maps of delay time based on the time needed to reach 50% of the maximal fluorescence intensity. In addition, it is possible to study the curves of fluorescence detected by the camera over the time of ICG-VA registration for multiple ROIs.

The first authors to explore the use of microscope-integrated quantitative analysis of ICG-VA for blood flow assessment were Kamp et al. (Kamp et al. 2012), who studied 30 patients with neuro-vascular pathologies, and were the first to hypothesize the possibility of using the different parameters derived from FLOW 800 analysis in clinical applications. In particular they showed that the maps of delay time could be of great value in giving an immediate representation of blood flow perturbation in cortical areas, either as an effect of the disease itself, or due to iatrogenic damage to arteries manipulated in the surgical approach.

Despite several applications of ICG-VA have been described so far (Dashti et al. 2009; De Oliveira et al. 2008; Ferroli et al. 2008; Imizu et al. 2008; Killory et al. 2009; Li et al. 2009; Woitzik et al. 2009; Xu et al. 2010), it is remarkable to note the paucity of articles reporting its use along with quantitative analysis to explore cerebral perfusion in the intraoperative setting (Ye et al. 2013; Uchino et al. 2014). Even less interest could be found in the context of surgery for brain tumors, where only cerebral and spinal hemangioblastomas have been studied (Hojo et al. 2014; Takeshima et al. 2015; Benedetto, Aquila, and Vannozzi 2013).

In 2009, when we acquired the technology to use the FLOW 800 algorithm for flow analysis, we started to systematically use ICG-VA with the new software, not only in vascular cases, but also during CNS tumor removal. Our population consisted of a heterogeneous group of cerebral and spinal tumors, represented mainly by meningiomas and high-grade gliomas. The most frequent application was an analysis of the arterial and venous patency, and brain perfusion, during or after tumor resection. In most cases, this evaluation confirmed arterial and venous patency and the absence of local hypoperfusion, thus reassuring us on the low risk of postoperative complications related to vessel manipulation. On the contrary, in few situations, the postoperative analysis showed local hypoperfusion directly related to

vessels manipulation. The intraoperative recognition of this complication allowed the surgeon to perform compensatory surgical maneuvers to immediately revert the local hypoperfusion and reduce the risk of postoperative complications (Acerbi, Cavallo, and Ferroli 2016; Ng et al. 2013; Kobayashi et al. 2014). Even though this task could be performed also with classic ICG-VA, as already reported in our previous experience and in a similar study by other authors (Ferroli, Acerbi, Albanese, et al. 2011; Kim, Cho, Chang, et al. 2011), the analysis of blood flow by FLOW 800 software allowed to better interpret brain perfusion, particularly with maps of delay times, as reported also in the vascular field (Kamp et al. 2012).

The preoperative analysis was used to identify both specific tumor-related pathophysiologic vascular changes and non-specific mass-effect changes. This was particularly important in glioblastomas and hemangioblastomas, where the superficial vascular pattern and the presence of arterovenous fistulae could be clearly shown. When dealing with arterialized veins, we tried to selectively sacrifice only arterovenous fistulas directly causing venous arterialization, always checking at the end of the procedure the normalization of venous flow.

The possibility to identify feeding arteries and the tumor nodule in hemangioblastomas was reported also by Hojo et al. in 2014 (Hojo et al. 2014), but mainly with classic ICG-VA. However, we believe that also for this application the use of semiquantitative flow analysis can improve and simplify the interpretation of videoangiographic data. Furthermore, preoperative analysis and long recording time allowed to concentrate the attention on the venous flow and, when needed, to perform a temporary clipping test to decide whether or not a vein could be sacrificed to enlarge the surgical corridor and/or completely resect the tumor, as shown by our group in a preliminary experience in 8 cases (Ferroli, Nakaji, et al. 2011). As underlined by Morcos and Munich in 2018 (Morcos and Munich 2018), the temporary clipping test can be thought of as a “provocative” test – the venous equivalent of the “balloon test occlusion” – to determine if a given vein can be sacrificed.

In our experience, although in the minority of cases, we also dealt with tumors approached with the patient in a semisitting position. Also in these cases, we could recognize the different flow patterns of draining veins (predominantly supracerebellar veins) and temporary clipping test could be performed as in the supratentorial district. Theoretically, there should have been a difference in flow characteristics for veins exposed in the posterior fossa when the patient is in the semisitting position, due to the position of the head in relation to the heart and the reduced central venous pressure. Nonetheless, in all patients in whom surgery was performed in this position, we tried to maintain a positive central venous pressure in order to reduce the risk of venous air embolism; thus, this could be one of the reasons why there was no clear difference in venous flow characteristics. We never performed an arterial clipping test for arterial sacrifice, as proposed by Kim and Cohen-Gadol in 2013 (Kim and Cohen-Gadol 2013), but we believe that this application is worth expanding in the future.

An innovation compared to previous experiences was also the utilization of ICG videoangiography in spinal tumors as a way to help in posterior median sulcus identification when the tumor was not abutting the spinal cord surface, or when, due to edema and congestion, the normal anatomy was distorted and the sulcus was difficult to find with white light illumination.

Finally, we were also able to show, in very selected cases, that an extradural analysis was feasible and it allowed the identification of dural sinuses and cortical veins, thus helping in

dural opening, as already shown by Nussbaum et al. (Nussbaum, Defillo, and Nussbaum 2012).

ICG-VA presents some technical limitations, independently from which field of neurosurgery it is applied to (vascular, oncological, spinal, etcetera). Most authors agree that the major drawback of ICG-VA is that it captures only what is visible within the field of the surgical microscope (Acerbi et al. 2019) and, as a consequence, it requires that the vessels must be cleared of any overlying tissue, such as blood clots or cottonoids (Killory et al. 2009; Hänggi, Etminan, and Steiger 2010); in addition, also calcifications within the vessels could impede a correct evaluation of blood flow. The meticulous and sometimes difficult dissection of tumor-related vessels, which is a precondition to use ICG videoangiography, can be a time-consuming process.

Secondly, experience demonstrated that ICG-VA usefulness is decreased in deep-seated lesions that must be approached through a long, narrow surgical corridor. In this setting, the signal and illumination can be low and the limited depth of field can make interpretation difficult (Killory et al. 2009; Hänggi, Etminan, and Steiger 2010).

Furthermore, the classic ICG method is purely qualitative and its interpretation is based on the judgement of the operating neurosurgeon without any objective measures. Only with the introduction of the software FLOW 800, ICG video-angiography became a reliable method to evaluate vascular and regional cerebral cortical blood flow during surgical procedures (Kamp et al. 2012); however, again, it requires more time to be performed and interpreted (in our series a mean of 7.9 minutes longer than classic ICG total time).

Finally, even though both classic ICG-VA and FLOW 800 software, do not have a steep learning curve, some training is still necessary to acquire the skills to use them and to interpret the results; in neuro-oncological surgery, we suggest starting with superficial analysis on veins flow in order to familiarize oneself with the technique and thereafter proceed to the clipping tests and to the intra-resection and post-resection evaluation of arterial flow.

Of course, we are aware of the fact that, in this chapter, we are presenting a retrospective evaluation of the different applications of ICG video-angiography with FLOW 800 analysis, based on the specific experience of our group. In addition, we did not perform any comparison with other techniques of blood flow monitoring, thus we could not provide any information about sensitivity and specificity.

Nonetheless, we believe that the results of this work underline the concept that surgery of brain tumors is also a surgery of brain vessels, and that understanding the pathophysiologic changes of brain circulation, due to the tumor presence and sometimes to the surgical manipulation, as derived by flow analysis provided by ICG video-angiography with FLOW 800 analysis, can be associated with better surgical results in selected cases.

CONCLUSION

Complete and real-time data on vascular pathophysiology represent a key point in modern neurosurgery that should be undoubtedly evaluated not only in neurovascular cases. We found ICG-VA with FLOW 800 analysis to be a useful technique to monitor blood flow in the exposed vessels and parenchyma during microsurgical removal of CNS tumors in selected cases and to guide the decision-making process regarding planned venous sacrifice or

unintended arterial damage, with a possible impact on the reduction of surgical complications. In particular, a pre-resection analysis provides useful information about pathophysiological changes of brain vasculature related to the tumor and individuates helpful landmarks for the surgical approach, while a post-resection analysis may help to prevent potential complications associated with the resection (such as local hypoperfusion or venous infarction). Future systematic studies comparing also other methodologies of blood flow monitoring are warranted to confirm all the potential advantages of this technique in the surgical management of CNS tumors.

Chapter 110

THE APPLICATION OF INDOCYANINE GREEN VIDEOANGIOGRAPHY AS AN ADJUNCT FOR ARTERIOVENOUS MALFORMATION SURGERY

ABSTRACT

Visualizing the anatomy and angioarchitecture of an arteriovenous malformation is important for their successful microsurgical removal. Resection ideally proceeds with pruning of arteries first, then the nidus, and finally the veins, while preserving normal en passage arteries. Indocyanine green has particular properties as a fluorophore and pharmacodynamics that make it useful as an intravascular contrast agent that can be visualized in vessels and their flow under the view of the operating microscope. Indocyanine green videoangiography can provide additional information that correlates anatomy and flow which the surgeon can use to assist in resection. This chapter describes the key attributes of indocyanine green angiography and contrasts it with digital subtraction angiography. Herein we also review the studies that have been published detailing the available experience with this technique in the surgery of arteriovenous malformations.

Keywords: arteriovenous malformation, indocyanine green, videoangiography, microsurgery, angiography

INTRODUCTION

Visualizing anatomical relationships and angioarchitecture is crucial during surgery for the resection of arteriovenous malformation (AVM)s. Magnetic resonance imaging (MRI), doppler sonography, computer-assisted navigation, digital subtraction angiography (DSA), and indocyanine green (ICG) videoangiography have all been used to improve intraoperative visualization of the vascular networks and structures of AVMs. While DSA is the gold standard for interrogating neurovascular structures, intraoperative ICG imaging has become widely adopted for its speed, safety, and superior capability for identifying vessels by their flow timing and for resolving very small vessels in the operative field with a surgical microscope. This chapter will examine the pharmacology, history, methodology, and use of ICG as an adjunct for AVM resection surgery.

PHARMACOLOGY

Indocyanine green (C₄₃H₄₇N₂NaO₆S₂) is a sterile, water-soluble tricarbocyanine dye that contains less than 5.0% sodium iodide. ICG is an infrared fluorophore, with a peak spectral absorption and emission of approximately 800 and 850 nm, respectively. Globulins are the major carriers of ICG in human plasma, specifically alpha-1 lipoproteins. There is negligible renal, peripheral, pulmonary, and cerebrospinal fluid (CSF) uptake, and ICG is not absorbed by the intestines or excreted by the kidneys. Excretion occurs hepatically by biliary secretion after uptake via hepatic parenchymal cells. The half-life is 3-4 minutes [1]. Doses can be given 5-10 minutes apart and visualized in real-time using a near-infrared (NIR) camera [2]. The recommended dose is 0.2-0.5 mg/kg, with a maximum daily dose of 5 mg/kg [1]. The most common clinical dose is 25 mg.

Adverse reactions to ICG are comparable to other contrast materials with a severe reaction rate of 0.05% and mild to moderate reaction rate of 0.15%-0.2% [3, 4]. Because of the small sodium iodide content, it should be administered with caution in patients with a history of sodium iodide allergy. Mild and moderate adverse reactions are classified as transient and pseudo-allergic, possibly due to non-immunologic release of histamine or other inflammatory mediators. Common non-life-threatening reactions include nausea, vomiting, sneezing, urticaria rashes, nerve palsy and localized tissue necrosis with complete resolution of symptoms after appropriate medical treatment [4]. No adverse sequelae were observed after resolution of mild to moderate reactions [4]. Severe reactions are classified as allergic-like, possibly due to a hapten-protein complex recognized by IgE, leading to mast cell degranulation and manifesting as anaphylactic shock with associated cardiopulmonary arrest or seizures [4]. Severe reactions do not appear to be dose-dependent and should be treated with appropriate medical protocol corresponding to the nature of the reaction [4]. Adverse reactions can be observed in patients without any history of iodine allergies [4]. Table 1 is a summary of ICG's pharmacological profile.

Table 1. Characteristics of ICG for neurosurgical use

Route of Administration	Intravenous
Excitation/Emission wavelengths	800 nm excitation, 850 nm emission
Dose	0.2-0.5 mg/kg
Maximum Dose in 24 hours	5 mg/kg
Clearance	5-10 minutes
Carrier protein in blood	Alpha-1 lipoproteins
Clearance System	Hepatic
Half Life	3-4 minutes
Rate of Adverse Events - mild/moderate	0.15-0.20%
Types of Adverse Events - mild/moderate	Nausea, vomiting, sneezing, urticaria, rashes, nerve palsy, localized tissue necrosis
Treatment Adverse Events - mild/moderate	Appropriate medical management of symptoms
Rate of Adverse Events - Severe	0.05%
Types of Adverse Events - Severe	Anaphylaxis, cardiopulmonary arrest, seizures
Treatment of Adverse Events - Severe	Appropriate medical management of symptoms
Recommended use	Superficial, complex vascular abnormalities
No evidence for use	Deep vascular abnormalities out of surgical microscopic visual field
Contraindications	Known allergy to ICG

HISTORY OF INDOCYANINE GREEN DYE USE IN AVMS

Neurosurgical intraoperative fluorescent vascular imaging began with the use of fluorescein, a fluorescent dye similar to ICG, in 1967 by W. Feindel [5]. Four years later, the same group would publish their results from implementing fluorescein in an AVM surgery [6]. It was the first recorded application of fluorescein in vascular neurosurgery [7]. Fluorescein was used with fluoroscopy and provided sharper contrast and finer detail compared to a subtraction angiogram alone, especially of the capillary and venous phases, demarcation of tumors, and visualization of vessels of all sizes of the epicerebral vessels (surface vessels including the pial arteries and veins, perforating branches, and superficial cortical capillary beds). The first human cases with fluorescein use included an occipital lobe angioma, atrophic cortex causing severe electrographic epileptogenic abnormalities, and a malignant glioma [5]. The usefulness of intraoperative fluorescein motivated neurosurgeons to identify additional fluorophores with intraoperative utilities. One option they turned to was ICG, which was originally approved by the Food and Drug Administration (FDA) in 1956 for cardiovascular applications. Recent studies show ICG produces similar information to fluorescein, with some differences based on differences in the chemistry. In general, ICH is more useful for elucidating hemodynamic information and benefits from being repeatable, whereas fluorescein has extended uses in tumoral applications [8]. The half-life of fluorescein is much longer than ICG and at usual doses is used only once per procedure. ICG's rapid clearance allows for multiple injections during a procedure [8].

ICG has been predominantly used in ophthalmology to assess retinal microcirculation [9]. ICG has also been used in plastic surgery to evaluate intraoperative flap perfusion and in gastrointestinal surgery to assess blood flow during anastomosis procedures [2]. In

neurosurgery, ICG is recognized for its use in identifying residual aneurysm perfusion, AVM nidi, spinal dural arteriovenous fistulae, arteriovenous shunting, patency of arteries, and for confirming the adequacy of collateral blood flow and patency after cerebrovascular bypass [2, 9]. ICG is useful in distinguishing AVM vessels (early arteries and veins) in real-time, therefore providing intraoperative guidance. However, ICG is restricted to the field of view through the microscope, making it less useful for deep AVMs that must be accessed through a narrow corridor or vessels outside the surgeon's direct visual field [10]. A cerebral ICG videoangiography run can be completed in less than one minute, and the results are available for review within 2 minutes, allowing for immediate action or correction of a procedure, such as temporary clip re-positioning in a time frame that should precede ischemia. The high spatial resolution from ICG allows for observation of patency of all vessels within the surgeon's view [10].

METHODOLOGY/INTRAOPERATIVE APPLICATION

As noted previously, the recommended range for individual doses is between 0.2 to 0.5 mg/kg, with a maximum dose of 5 mg/kg/day. ICG can be administered multiple times at the surgeon's discretion, with an average of 5-10 minutes between injections. The microscope can be switched back to near-infrared visualization mode to check if it has cleared. Note that is not necessary for the ICG from a prior dose to have cleared completely, as the brightness of the new dose overwhelms the partially metabolized one. Typically, ICG is administered once to visualize the arteriovenous malformation prior to resection, at least once while the pathology is being addressed, and then once after what is presumed to be complete surgical treatment and before closing to ensure complete resolution of vascular pathology [1]. While lack of AVM on ICG does not obviate the need for an angiogram, the presence of early draining vessels should prompt further surgical exploration prior to the angiogram.

During an ICG videoangiographic run, near-infrared light from a modified microscope light source is passed onto the surgical field, then ICG fluorescence is passed back from the surgical field into the optical path of the surgical microscope. The light illuminating the field has a wavelength covering part of the ICG absorption band (700-850 nm, absorption peak 805 nm) and the returning fluorescence is recorded by a nonintensified charged coupled device (CCD) camera (780-950 nm, emission peak 835 nm) [1, 10, 11]. The microscope has an optical filter that blocks ambient and excitation light allowing only ICG-induced fluorescence to be collected. ICG's integration into NIR imaging allows for speed adjustment of the video feedback, allowing the surgeon to watch a slowed version of ICG angiography as well as real-time feedback [1]. Angiographic images are displayed on a video screen in real-time and recorded for later review [11]. One disadvantage of NIR-imaging is the inability to visualize fluorescence directly through the microscope ocular lens, but rather on a monitor. Some newer commercial systems allow the ICG signal to be displayed in the oculars as a ghosted overlay (Figure 1).

Figure 1. A microscopic view of a small pial AVM shows the ICG videoangiogram as a superimposed yellow overlay on the microscope image.

INDOCYANINE GREEN DYE AND ARTERIOVENOUS MALFORMATIONS

AVMs can be anatomically complex, making incomplete resection one of the most common complications of AVM surgery [12]. AVM resection requires dissection of intricate structures to control feeding arteries and isolation and resection of the nidus, necessitating the use of high-power imaging studies, such as DSA and ICG [12]. To better estimate the risks of operating on an AVM and to determine operative morbidity and mortality, R. Spetzler and N. Martin created the Spetzler-Martin (SM) grading system [13]. A Grade I AVM has the lowest grade with relatively minor technical difficulty and low risk of morbidity or mortality. A Grade V AVM has the highest grade, indicating significant risk of morbidity and mortality, due to the large size, the close proximity to important/eloquent brain regions, and the presence of deep draining veins. There is a further grade, Grade VI or “inoperable,” that are very large, diffuse and dispersed through critical areas, or encompassing critical structures that would be associated with disabling deficit or death upon injury [13].

As the Spetzler-Martin Grading System suggests, there is a great need for accurate visualization of AVMs of varying complexity. Intraoperative supplementation of DSA with ICG can be used to temporally distinguish AVM vessels based on fluorescence. Arteries fluoresce first within 3-12 seconds following intravenous injection, followed by arterialized veins, and finally cortical (non-arterialized) veins [1]. ICG can also be helpful in identifying small, ruptured AVMs in hematoma cavities once the hematoma has been evacuated to allow for visualization of the cavity walls. In a study by Killory et al. [1] of 10 patients with AVMs ranging from Grades I to IV, ICG angiography was performed before resection, at least once during, and after the resection. The surgeon was able to clearly distinguish vessels and arteriovenous shunting, discern AVM arteries, draining veins, and cortical veins. ICG was helpful in 9 out of the 10 cases; one AVM was located deep, and approached through a narrow corridor, only allowing for portions of the lesion to be visualized. In 3 procedures, the surgeon was confident enough with the ICG results to forgo intraoperative DSA results and only conduct postoperative DSA [1].

During AVM resection, ICG can be utilized at three stages: first, a primary superficial survey can be performed prior to resection to obtain identify the AVM and to provide information about superficial angioarchitecture and flow dynamics (Figure 2). It can also be used as resection progressed during resection with as-needed repeated boluses to obtain hemodynamic information on en passage feeders, and terminal assessment at the end of the resection to identify residual AVM. Hanggi et al. [12] studied 46 AVM and dural arteriovenous fistula procedures with ICG and found that 41 ICGs were rated excellent, 2 intraoperative ICG injections provided information that changed the surgical procedure, and 16 out of the 17 AVM postoperative DSA results corresponded to the postoperative ICG results. In one procedure, the terminal assessment was inconclusive due to insufficient illumination of a deep thalamic AVM. The primary superficial ICG survey that was conducted in 12 cases (excluding deep AVM cases) provided additional information and orientation of the nidus, terminal and en passage feeders. In 14 of the 18 intraoperative injections, ICG provided information on the localization of en passage feeders, the integrity of adjacent arteries, and the location of AVM compartments. Eleven postoperative injections observed early filing of the major draining vein and allowed for detection or exclusion of residual nidus [12].

Figure 2. (Continued).

(E)

Figure 2. A. A close-up view of the pial surface in a patient with subarachnoid hemorrhage from the underlying AVM. Blood obscures much of the AVM. B. The ICG run clearly shows the AVM through the blood and identifies both a feeding artery (arrow) and draining vein (arrowhead). C. A view of the cortex showing a different patient with a left frontal AVM in early phase. The arrow indicates an early-filling loop which can therefore be identified as an artery which feeds the AVM. D. A middle-phase run shows arterialized veins filling next (arrow). E. The late phase shows all of the AVM vessels filling, and in the normal draining veins there is some early drainage from the AVM in these veins seen as a slipstream (arrow).

In a retrospective review of 130 AVM resection cases (56 ICG and 74 non-ICG), Zaidi et al. [14] determined that ICG was used more frequently in lobar and cortical surface AVM resections, and less frequently in cases with deep arterial supply to the nidus and posterior fossa. The SM Grade between the ICG and non-ICG groups were similar (2.2 vs 2.4), with the same AVM diameter (2.7 cm) in both groups. There was no statistical decrease in the incidence of residual disease with ICG use or statistical differences in modified Rankin Scale scores preoperatively, postoperatively, or at last follow up. There were no complications attributed to ICG use [14].

ICG can also be used in atypical AVM resections. In one case, a patient presented with a small cerebellar AVM resembling a posterior fossa cavernous hemangioma on preoperative imaging. MRI results were equivocal, and angiography confirmed a Grade I AVM. ICG was used pre-, intra-, and post-resection [15]. Pre-resection ICG infusion displayed a “blackberry-like” appearance with tiny surrounding vessels lacking the basement membranes and astrocyte foot processes of the blood-brain barrier. ICG videoangiography was noted to be helpful in guiding surgical approach, especially prior to dissection where video playback was used to distinguish venous and arterial phases and allowed for real-time analysis and understanding of the unique AVM features.

ALTERNATIVE USES AND METHODS OF INDOCYANINE GREEN DYE

ICG can be used with FLOW 800 (Carl Zeiss Co) microscopic analysis to provide increased information about blood flow dynamics. Without FLOW 800, recognition of feeders from draining vessels can be determined based on the chronological order after injection, but FLOW 800 provides additional pseudocoloring to map blood flow dynamics and distinguish between feeding arteries, draining veins, and normal arteries along with

intensity diagrams to document blood flow. Temporal fluorescence maps can be used to visualize the direction and sequence of blood flow with color coding based on velocity to allow for temporary clip placement and observation. Comparative analysis of curves showing variations in blood flow over time in a certain region can be utilized to determine the completeness of surgical resection. As with ICG alone, this method is limited in deeply located lesions [16].

Acerbi et al. examined venous flow intraoperatively in pathological and normal veins over a variety of procedures, including 16 AVMs, and were able to characterize five different venous patterns: 1. arterialized veins with flow characteristics similar to arteries (observed in all 16 AVMs), 2. thrombosed veins with retrograde flow (observed in a left temporal glioblastoma), 3. fast and homogeneously filling fast bridging veins and anterograde flow towards the usual draining sinus, 4. slow and non-uniform filling slow bridging veins with anterograde flow with multiple tributaries and one large collector close to the sinus with multiple velocities, 5. and slow bridging veins with retrograde flow in the direction opposite the sinus (observed in parasagittal meningiomas). After the procedure, they were able to use ICG to confirm the normalization of venous flow in arterialized veins or only retrograde flow from normal continuous veins, including in all 16 of the AVMs, as well as confirm good collateral circulation in select cases [17].

DIGITAL SUBTRACTION ANGIOGRAPHY AND ARTERIOVENOUS MALFORMATIONS

From the 1960s to the 1980s, the value of intraoperative angiography became more widely acknowledged as beneficial for avoiding errors and for tracking procedure progress. Previous techniques were known for being expensive, cumbersome, requiring large amounts of contrast medium, and excessive time for film development. The development of DSA simplified this process [18]. In DSA, x-rays are passed through the patient's body to a photoelectric receiver that then converts the x-rays into electrical signals. When these digital impulses are amplified, they can be assembled into real-time images allowing immediate review at normal, slow, and frame-by-frame speeds [18, 19]. There are three types of DSA: temporal subtraction, energy subtraction, and hybrid subtraction [20]. Temporal subtracted is constructed by subtracting single or integrated images (a "mask") from images with contrast medium obtained at different times and may contain artifactual changes resulting from incomplete subtraction due to movement. Energy subtraction results from images produced by high and low energy x-ray pulses that are digitized and may be more useful in the abdomen or regions with more overlying bony structures. Hybrid subtraction utilizes energy subtracted images as a sequence for temporal subtraction and reduces movement artifacts.

Modern DSA through femoral or radial artery access allows for macroscopic resolution with reduced amount of contrast medium and radiation doses for both the patient and the surgeon compared to carotid or vertebral angiography and traditional intraoperative x-ray, as well as elimination of direct puncture of the carotid artery [19]. In a study to examine intraoperative angiography in the management of several different neurovascular disorders, D Barrow et al. noted that out of 39 AVM resections, DSA revealed some residual malformation during 6 of the procedures. While DSA provided the ability to recognize and correct technical

defects and reduce the risk of another operation and post-operative complications, they did note that DSA added 30-60 minutes to each procedure [18]. The rate of complications with DSA use is 1 to 3%, and can include permanent neurological deficits including embolism and carotid dissection [21].

COMPARISON OF INDOCYANINE GREEN DYE AND DIGITAL SUBTRACTION ANGIOGRAPHY

DSA has been shown to be useful in the detection of AVMs in a patient undergoing emergent hematoma evacuation, and in distinguishing AVMs from normal nutrient carrying, or “en passage” vessels [1]. It also remains the most accurate for large, complex aneurysms [11] or deep AVMs, and is the gold standard for confirming AVM resection. Despite this, DSA use is expensive, technically demanding, and requires major logistical support. Administration of the contrast medium and acquisition of the images is an invasive and time-consuming process [1]. There is risk of potential vascular or neurological injury along with complications due to increased operating time [1].

With the development of technological advancements, ICG has become more prominently used due to the ability to quickly integrate vital information about vessel patency and flow during an operation, low cost of use and absence of additional equipment required other than microscope software modifications, and low to no morbidity [22]. ICG can be used to determine immediate action for correction of aneurysm clip position and is easily repeatable before, during, and after a procedure. While results for DSA can take upwards of 20 minutes, ICG results are available within 2 minutes. Since most surgery-related complications result from injury to arterial branches of the normal tissues or incomplete resection [12], use of ICG could theoretically contribute to a reduction in morbidity. ICG is best utilized with smaller, low grade and superficial AVMs where the integrity of the AVM and the resection cavity is readily observable. The surgeon is unable to see ICG fluorescence through blood clots, aneurysms, brain tissues, or outside of the field of view of the microscope, leaving the possibility of a nonvisualized remnant. Calcification, thick-walled atherosclerotic vessels, or partially or completely thrombosed aneurysms can also obstruct fluorescence [11, 14].

In a study comparing DSA to ICG, Bilbao et al. reported that ICG was useful for distinguishing AVMs in 26 out of the 32 patients with AVM Grades I to IV. In 9 of the 16 patients, ICG allowed for differentiation of en passage vessels from malformation-based pathological vessels. ICG missed three out of four residual AVMs, compared to intraoperative DSA that only missed one, confirming ICG’s use in small, superficial AVMs but decreased efficacy with deep, high grade AVMs [14, 22].

Given this data, reasonable applications of ICG in AVM surgery are 1) as an initial tool to distinguish feeding arteries from draining veins, so as to guide the order of resection, 2) to identify en passage arteries and distinguish them from primary AVM vessels, and 3) as a screening tool to look for residual AVM and track the progress of resection, recognizing that a negative result does not exclude residual AVM.

CONCLUSION

Indocyanine green videoangiography has been shown to provide safe, fast, and vital information that can be used intraoperatively to identify en passage and pathological vessels, measure vessel patency, and determine complete AVM resection. As a water-soluble infrared fluorophore, ICG dye has limited renal or intestinal excretion and has a high safety profile with an allergic reaction rate under 0.2% and a severe allergic reaction rate of 0.05%. The recommended injection dose is 0.2-0.5 mg/kg and with a maximum daily dose of 5 mg/kg. ICG is a formidable video angiographic technology with a capacity for multiple injections during procedures and decreased time to results. The integration of ICG fluorescence information into the surgical microscope revolutionized the ease of use of ICG at all stages of a procedure, and additional technological advances, such as FLOW 800 software, continue to expand ICG applications. However, the use of ICG is limited to the surgeon's visual field, making it less useful for deep AVMs but adequate for superficial vascular pathologies. Although it cannot replace DSA in certain cases, the advantages of ICG can possibly be used to complement DSA angiography. In the scope of ICG videoangiography in AVM resection, further research is needed to establish protocols for combined IGA and DSA use. As ICG use becomes more prevalent and surgeons become more accustomed to using ICG videoangiography in AVM resection and other procedures, ICG will become more prominent both as a stand-alone technique and in conjuncture with DSA.

Chapter 111

CURRENT TRENDS IN FUNCTIONAL MUSCLE TRANSFER TO IMPROVE OUTCOMES IN FACIAL REANIMATION SURGERY

Ioana Lese* and Adriaan O. Grobbelaar

Department of Plastic, Aesthetic and Reconstructive Surgery
Inselspital, Bern University, Bern, Switzerland

ABSTRACT

A spontaneous and symmetrical smile is the goal of long-lasting facial paralysis surgery. Even though two-stage free functional muscle transfers are considered the gold standard treatment, only about 60% of patients get a perfect symmetrical smile in response to emotion. Under or overactivity of the transplanted muscle is an unpredictable surgical phenomenon contributing to inferior surgical outcomes. Surgeons and researchers attempt through continuing research and the development of novel surgical strategies to improve the reliability of functional muscle transfers. Terzis first popularized the babysitting procedure of the damaged facial nerve by a partial hypoglossal transfer to protect the muscle end plates until the facial nerve can recover or a cross-facial nerve can innervate the facial muscles. Various supercharging procedures with sensory nerves have been suggested as a protection mechanism for the muscle and also for the nerve graft while the motoneurons reach their final target. The dual-innervation concept relies on a second neural input to serve the cross-facial nerve graft until the new motor axons from the contralateral facial nerve reach the recent paretic facial musculature. In this chapter, we will attempt to discuss current trends in re-innervating functional muscle transfers and the neurophysiological basis for these various techniques.

1. INTRODUCTION

Reconstruction of the middle and lower face in long-lasting facial paralysis implies restoration of spontaneous and symmetrical smile, as well as symmetry at rest. The gold

* Corresponding Author's Email: ioana.lese@gmail.com.

standard treatment is considered a two-stage free functional muscle transfer [1], but lack of a consistent, reproducible result still eludes the surgeon and patients. It is generally accepted that only 60% of patients get a perfect symmetrical smile in response to emotion [2]. Under or over activity of the transplanted muscle are the most common presentation in patients that do not achieve excellence [3]. Basic knowledge and understanding of nerve physiology is still lacking. Is there an ideal nerve size/muscle ratio for the transplanted muscle to function optimally? Organization patterns of the motor axons pre and post neurotomy can now be examined with the concept of connectomics [4].

Baby-sitting of the damaged facial nerve is a novel technique employed in the surgeons' armamentarium to improve ultimate results [5]. The partial hypoglossal nerve is connected in an end-to-side technique to the damaged facial nerve, while multiple cross-facial nerve grafts are connected to the contralateral healthy facial nerve. The distal ends of these grafts are later, in a second stage, connected to the distal branches of the damaged facial nerve. The partial hypoglossal nerve is thought to provide endogenous growth support to the denervated distal nerve stump.

Surgeons try to enhance facial reanimation outcomes by supercharging the cross facial nerve graft with sensory nerves postulating that it has a protective capability [6]. These sensory-to-motor innervations exerted trophic effects on the muscle and also maintain the architecture of the distal nerve stump until the reinnervated axons are able to reach their target.

Dual-innervation is yet another method explored in order to produce a more repeatable result every time [7]. Through this technique, the spontaneous neural input provided by the contralateral facial nerve is combined with the great axonal load of the masseteric nerve, ensuring therefore a shorter reinnervation time, as well as a stronger muscle contraction.

The history of free muscle transfer for facial reanimation began in 1971, when Thompson described the first free muscle transfer for facial palsy [8]. He used the extensor digitorum brevis muscle, however without performing any vascular anastomoses or neurotomy. Subsequently, the muscle cells were replaced by fibrous tissue due to the lack of vascular inflow and neural input. Inspired by his and Tamai's work [9], Harii described in 1976 the first microvascular transfer of the gracilis muscle for facial reanimation [10]. He used the superficial temporal vessels and the deep temporal nerve as the recipient neurovascular pedicle. Later, he recommended the now standard two-stage procedure with a contralateral cross-face nerve followed by a functional free gracilis muscle transfer 9-12 months later [11]. In order to address the bulkiness of the gracilis muscle and the lack of sufficient contractile force of the extensor digitorum brevis muscle, Manktelow and Zuker developed the concept of 'functional anatomy' by separating the gracilis muscle into territories based on the individual fascicular nerve stimulation [12]. They proposed this technique as a way of trimming the muscle and therefore avoiding the postoperative bulkiness, as well as a way of achieving separate contractions within a single muscle. The same principle was applied by MacKinnon for the latissimus dorsi muscle [13]. The major problem of these trimming techniques is the risk of postoperative hematoma. In order to overcome this, an alternative muscle was described by Harrison [14] and Terzis [15]: the pectoralis minor muscle, which seems to offer just enough bulk, while also being able to provide good excursion.

When looking at recipient nerves, a spontaneous smile can only be achieved by the 7th nerve and is the desired choice of motor nerve for facial reanimation, especially in children. Other recipient nerves have been described, such as the accessory [16] and the hypoglossal

nerve [17]. The former, even though it offers a good neural input, the morbidity of sacrificing the nerve, as well as the lack of ability to respond to emotion has made its use fairly rare [18]. The latter also presents disadvantages such as hemiglossal atrophy and difficulty with speech. In order to overcome these shortcomings, Terzis introduced the minihypoglossal procedure in combination with a cross-face nerve, where only 40% of the hypoglossal nerve circumference was used, with little side effects [19, 20]. The masseteric nerve seems to be the most frequently employed nerve in one-stage procedures in adults or children with Moebius syndrome where bilateral facial palsy is present. The biggest problem with alternative motor nerves is the question of brain plasticity and whether patients ever develop a spontaneous smile. Manktelow et al. showed that spontaneous smile occurred in 59% of the patients undergoing facial reanimation surgery with gracilis muscle innervated by the masseter motor nerve, which was attributed to cerebral plasticity [21].

2. PARADIGM SHIFT IN FACIAL REANIMATION SURGERY

2.1. Baby-Sitting of the Damaged Facial Nerve

The baby-sitter procedure was first introduced by Terzis in 1984 [22] as a way of assisting the cross-facial nerve graft until the new motor axons from the contralateral facial nerve reach the recent paralytic facial musculature. It entails a 40% neurectomy of the hypoglossal nerve, with end-to-side neuroorrhaphy to the ipsilateral damaged facial nerve trunk, performed at the same time with the first stage of a cross-facial nerve graft. The second stage of the procedure has to be performed 8 to 12 months later, when the distal ends of the cross-facial nerve grafts are connected distally to the branches of the affected facial nerve.

Patients with recent complete clinical paralysis of the facial muscles and unusable proximal facial nerve are candidates for the baby-sitter procedure. Needle electromyography has to show signs of denervation, like fibrillations, in order for the patients to qualify for such a procedure. These translates in muscles that still have the potential to be resuscitated.

The standard treatment of patients where the proximal part of the facial nerve cannot be used to reanimate the facial musculature are nerve transfers, such as accessory, hypoglossal, trigeminal and phrenic nerve. All these transfers are associated with loss of function at the donor side ranging from minimal to significant, as well as uncoordinated mass movement

- accessory nerve – limited active shoulder abduction, severe shoulder pain and stiffness, shoulder girdle depression [23, 24];
- hypoglossal nerve – hemi-tongue atrophy with mastication problems, difficulty in swallowing and speech impairment [19, 25]
- trigeminal nerve – rare reports of temporary limited mouth opening, cheek thinning
- phrenic nerve - diaphragm dysfunction with dyspnea and sleep disturbances [26]

Moreover, these donor nerves are not capable of providing spontaneous emotional expression, apart from the masseteric nerve, where spontaneous smile could be recorded in some of the patients [21, 27]. These results are attributed to the cerebral cortical reorganization, a concept still not entirely understood. Nonetheless, latent pre-existing

horizontal connections between facial nerve and fifth nerve centers are believed to become active through learning exercises.

Since its first description by Sacramella in 1970 [28], the cross-facial nerve graft represents the first choice when it comes to reanimation of coordinated and spontaneous smile. The neural input provided by the healthy facial nerve cortical center enables the spontaneity and synchronicity of facial expression. However, this important breakthrough in the field of facial nerve paralysis still has a major shortcoming: the long distance for axon regeneration might take too long for the target muscles and reach them after atrophy has occurred [29], on the one hand, while there are theories stating that the chronic denervation of Schwann cells in the distal stump of the nerve has more impact on poor functional recovery than the irreversible denervation atrophy of the muscle [30]. Compared to the ideal situation where a direct immediate repair of a nerve takes place in close proximity of the target muscle and in the time window when the Schwann cells' neurotrophic support for axonal regeneration is optimal (1-8 weeks in animal studies [31]), only 10% of these regenerating axons crossing the suture line are present in a chronically denervated distal nerve stump. Moreover, Sulaiman et al. showed not only that this reduced number of regenerated motoneurons reinnervated the denervated muscle fibers, but they were able to reinnervate up to 3 times the number of muscle fibers that they normally do. Therefore, this enlargement of the reinnervated motor units made them conclude that it is not the inability of the denervated muscle fibers to be reinnervated that leads to poor functional recovery, but the chronic denervation of the Schwann cells that limits the number of regenerated axons.

In order to surpass this obstacle, Terzis envisioned the babysitter procedure using part of the hypoglossal nerve as described at the beginning of the section in order to provide endogenous growth support by adding motor donor axons into the denervated distal nerve stump. Depending on the need for additional procedures, she divided the patients in 3 groups [5]:

- A. Short denervation time (6-9 months denervation time) – the two-stage procedure should provide sufficient symmetrical animation, without the need for additional interventions
- B. Later cases (denervation > 9 months) – even though there are some fibrillations on needle electromyography, the patient should be warned that the need for additional muscle transfer is frequent
- C. Late cases (denervation > 24 months) – the baby-sitter procedure is still recommended, provided that sparse fibrillation potentials can be evoked; however, in this group, a free muscle transfer will certainly be needed in order to achieve satisfactory results

In the late cases, the baby-sitting procedure is believed to make the secondary procedures more successful, even if just minimal function of the autologous facial musculature returns.

In one study [20], 20 patients underwent the original baby-sitter procedure. Overall, all the patients achieved a degree of emotional and coordinated movement, with 10% recording an excellent result (symmetrical smile and full contraction), 16% a good result (nearly symmetrical smile and nearly full contraction) and 25% a moderate result. Postoperative eye closure and lower lip depression also recorded a significant improvement.

In another study pertaining to the same group [5], 18 patients underwent the baby-sitter procedure together with a free muscle flap (gracilis muscle or pectoralis minor muscle) or a regional muscle transfer (frontalis, platysma muscle). While all the free muscle flaps were performed during the second stage of the baby-sitter procedure, only part of the regional muscle transfers were performed at the same time. 10 patients needed an additional third stage for the regional muscle transfer. Eyelid closure, smile and lower lip depression seemed to record statistically significant improvement.

Since sacrificing the entire hypoglossal nerve, as in the classic hypoglossal transfer, leads to tongue atrophy with subsequent dysarthria and dysphagia [32, 33], Kalantarian et al. [19] investigated the number of fibers sufficient enough to restore eye sphincter function in a rat model of facial paralysis and blink reflex, but without sacrificing the vital function of the tongue. Nerve conduction studies and axonal counts in the hypoglossal nerve and motor end-plates showed a minimal atrophy of the tongue in the 40% group, while warranting sufficient reinnervation of the zygomatic branch. Since the 80% group lead to an excessive tongue atrophy, the group concluded that 40% neurectomy of the hypoglossal nerve ensures preservation of the tongue and adequate target function.

Apart from the mini-hypoglossal nerve, Bianchi et al. [34] described a modification of the baby-sitter procedure, where the masseteric nerve is coopted to the principal inferior branch of the facial nerve on the affected side, while 2 cross-facial nerve grafts are connected both on the healthy and the paralyzed side to distal zygomatico-ocular and zygomatico-buccal branches, therefore having just a one-stage procedure. All 8 patients achieved spontaneous and emotional smile, without biting, between 7 and 13 months postoperatively.

2.2. Supercharging the Cross Facial Nerve Graft with Sensory Nerves

Distal nerve stumps undergo Wallerian degeneration and Schwann cells play an important role in this process [35]. At the beginning, they are involved in the degeneration and phagocytosis of debris, such as axons and myelin. In a more advanced phase, the loss of axonal contact induces the Schwann cells to proliferate and change in phenotype from that of myelinating to a nonmyelinating, growth-supportive phenotype. Therefore, the myelin-associated genes are downregulated, while the regeneration-associated genes are upregulated [36]. This process is also known as chronic denervation. The same happens to a cross-facial nerve graft that can be over 20 cm long. The time needed for the axons to regenerate through them is several months, since axon growth rate was appreciated at around 1 mm/day [37].

Frey et al. [38] showed in an animal study on sheep that a high number of regenerated fibres, closer to the number of the fibre input by the motor donor nerve was present at the distal end of the sensory donor graft. Moreover, the median diameter of the healthy nerve fibers in the sensory nerve graft in the distal end, at 9 months, is around one quarter of the normal supplying motor nerve. However, this finding was not supported by their clinical study, where only 10 - 20% of the original sural nerve fibers were identified on the distal end.

Jacobs et al. [39] recorded a mean number of 426 myelinated fibers at the distal end of the sural nerve graft, compared to a mean of 1736 of the normal buccal branch of the healthy side used as donor. Even though only a small portion of the myelinated nerve fibers reach the distal end of the sural graft, very large numbers of unmyelinated axons regenerate (mean of 3853 in the buccal branch, compared to 11043 in the distal end of the sural graft). The authors

suggest that the functional free muscle transfer connected to the sural nerve graft in the second stage is evidence that these unmyelinated fibers have the potential to become myelinated once the target muscle is present.

Since results of free functional muscle transfer with cross-facial nerve graft are partial at best, Placheta et al. [6] envisioned a study where they could help with the chronic degeneration that takes place at the end of the cross-facial nerve graft due to the long distance and therefore duration of axonal regeneration. Their idea came from the babysitting [22] and sensory protection [40, 41] of chronically denervated nerves, both of the procedures providing endogenous trophic support, therefore improving regeneration. The sensory protection theory has been further investigated by Bain and collaborators [40, 41], based on previous studies which showed that sensory-to-motor innervation are incapable of forming excitable neuromuscular junctions, but they surprisingly exerted trophic effects on the muscle [42, 43]. In a rat model, they cut the tibial nerve before entering the gastrocnemius and soleus muscles and delayed the peroneal-tibial nerve transfer for 4-6 months. In one group, no sensory nerve was used, while in the second group ('sensory-protected'), the saphenous nerve was sutured in an end-to-end technique to the distal stump of the tibial nerve for these 4-6 months. In the end, the mean weights, twitch and tetanic tensions, as well as the histological appearance of the gastrocnemius and soleus muscles in the sensory-protected rats were always superior to the other group. Their assumption was that neurotrophins, produced by motor and possibly sensory nerves, might have effects on skeletal muscle fibers and maintain the architecture of the distal nerve stump. The same group further published the first clinical case of sensory protection in a patient with complete sciatic nerve palsy following hip arthroplasty. The patients underwent neurolysis of the sciatic nerve after neuroma formation and saphenous nerve transfers to the motor branches of the medial and lateral gastrocnemius muscles, as well as to the motor branch of the deep peroneal nerve to the tibialis anterior muscle. After 3 months, electromyography studies showed amelioration of denervation potentials and improved motor recovery only in these specific muscles.

Ladak et al. [44] tried to protect the distally denervated nerve stump with 1 to 3 side-to-side nerve grafts between an intact donor tibial nerve and the distal stump of the severed common peroneal nerve. The grafts were taken from the common peroneal nerve and the delayed surgical repair of the distal stump of the common peroneal nerve to the proximal stump took place several months after the initial procedure. After allowing the delayed surgical repairs to regenerate for 5 months, the common peroneal motoneurons had more regenerating axons in the denervated nerve stumps of the 'protected group' and the weight of the reinnervated muscles also registered higher values.

Since all of these experiments are hard to translate in the clinical setting, Placheta et al. [6] used regional sensory nerves in an end-to-side technique for the cross-facial nerve grafts in a rat model in order to enhance facial reanimation outcomes. The right common peroneal nerve was used as the cross-facial nerve graft. The right side of the face was considered the healthy one and the buccal branch of the facial nerve was used as the donor motor nerve for the cross-facial nerve graft. After passing the graft on the other side of the face, the distal end was sutured to the buccal and marginal mandibular branches of the facial nerve. In the sensory protection group, the 2 occipital nerves were dissected and sutured in an end-to-side technique to the cross-facial nerve graft in an epineural window at 10 and 20 mm from the proximal suture of the graft. The *in vivo* imaging of regenerating axons demonstrated that axons reached the left side of the face (recipient) earlier than the group where no occipital

nerves were used. At 16 weeks, the right facial nucleus showed more retrograde labelled motoneurons in the protected group. The same group registered higher amplitudes and higher velocity during retraction of the whisker movement analysis. These results were also supported by the histomorphometric analysis of the buccal and marginal branches on the left side, 10 mm distal to the branching. The mean number of myelinated axons was 1873 in the unprotected group, while the protected group with occipital nerves recorded a mean number of 2458 myelinated axons. Both of these values are higher than the mean of 1685 myelinated axons of the donor buccal branch on the right side, indicating axonal sprouting in these groups. Through this model, the authors intended to avoid a motor nerve deficit and also the overpower of the facial nerve impulses from the contralateral side through the introduction of another motor donor nerve. The end-to-side technique used is a modification of the supercharge nerve transfer already described in the literature [45-47]: the end of the donor nerve is coapted in an end-to-side manner to the injured recipient nerve in order to maintain the partially regenerated function of the recipient nerve and further augment it.

For example, Farber et al. [45] employed this principle in an incomplete rodent sciatic nerve injury model. The group where supercharging was performed in combination with normal grafting of the severed nerve showed more intense labelling of motoneurons in the ventral horn and also a higher number of myelinated fiber counts in the distal nerve. Therefore, this higher number of myelinated fibers cannot only be attributed to sprouting, since the more intense ventral horn motoneuron labelling indicated that the supercharged end-to-site transfer provided additional motoneurons to the target muscles. Moreover, this higher number of myelinated fibers correlated with a greater muscle specific force. On specific muscle force analysis, the supercharged end-to-site transfer group didn't drop to the values of the control group with normal grafts after sectioning of the supercharging donor. One possible explanation might be that even if both groups would have the same number of prime donor regenerated to the muscle, the supercharged group showed a better performance of the muscle due to protection from atrophy conferred by the transfer. Altogether, the supercharging procedure seems to preserve muscle function apart from motor neurons' delivery.

In another study, Isaacs et al. [47] compared muscle force in the gastrocnemius muscle after transection with primary repair (group 1) and transection with primary repair and supercharged end-to-side transfer of the peroneal nerve (group 2). After elimination of potential regenerative pathways in the second group, proximal stimulation showed that both axonal pathways determined notable reinnervation. Another study of the same group concluded that a supercharged end-to-side transfer to a non-injured, non-transected recipient nerve didn't account for any part of the muscle force recorded in the recipient's target muscle [48].

2.3. Dual-Innervation

Since first described by Harii in 1976 [10], free functional muscle transfer is considered the gold standard treatment of long-standing facial paralysis. However, when used in conjunction with a nerve other than the facial nerve, like for example the masseteric nerve, the voluntary clenching of the teeth needed as stimulus and the inability to achieve coordinated movement with the healthy side of the face led to the development of the nowadays standard procedure: two-stage cross-facial nerve graft (first stage), followed by the

transfer of a free functional muscle (second stage) as described by O'Brien [49] and Vedung [50]. The main advantage of the cross-facial nerve graft is the ability to provide synchronous and spontaneous activity of the free muscle transfer, while its unpredictability and lack of consistency in muscle contraction degree are considered its main drawbacks [51]. An explanation for the latter might be the lower number of axons reaching the target muscle due to the fact that they have to cross two neurotomy sites [52]. Moreover, the long time required for the two-stage procedure was also seen as a disadvantage. In order to reduce this time, but still maintain the spontaneous and synchronous impulses coming through the non-paralyzed 7th cranial nerve, Koshima [53] and Harii [54] envisioned a one-stage free functional muscle transfer with a long nerve, connected directly to a branch of the healthy facial nerve. While the rectus femoris muscle used by Koshima achieved adequate contraction, the bulk of the flap was seen as an impediment of this technique. To overcome this aspect, Harii used the segmental latissimus dorsi muscle. Even though the aesthetic results were better, the predictability of the amount of contraction couldn't be guaranteed.

Another well-established technique is the free gracilis muscle flap anastomosed to the masseteric nerve [55]. The main advantage of this procedure is the short period of time needed for the reinnervation of the flap, apart for the single-stage aspect. Moreover, the reliability of the masseteric nerve and its contractibility in 100% of the cases was also reported by Manktelow et al. [21]. In the same study, the authors reported the presence of spontaneous smile in 59% of the patients, as described by the ability of the patients to smile involuntarily in over half the time or more. This finding was attributed to cerebral cortical reorganization (a process also known as cortical adaptation) through the activation of dormant horizontal connections [56] or the appearance of new synaptic connection [57] between the fifth nerve center and the facial nerve center. However, identification of these connections with functional magnetic resonance imaging wasn't possible due to the close proximity of these two centers in the cortex.

The first description of a dual-innervation technique was provided by Watanabe et al. [58]. The authors transferred a free functional latissimus dorsi muscle with a long thoracodorsal nerve (15 cm) to the paralyzed face, while the nerve was tunneled through the upper lip to reach the healthy, contralateral side where it was coapted to a buccal branch of the facial nerve. Additionally, they removed the soft-tissue of the hilum where the thoracodorsal nerve entered the latissimus dorsi muscle, as well as the soft tissue present over the masseter muscle. The two 'raw' surfaces were then placed in contact. Voluntary movement was recorded at 3.4 months, while spontaneous smiling was achieved 5.9 months postoperatively. The benefits of their technique consisted, among others, in a faster reinnervation of the latissimus dorsi muscle than a standard one-stage technique and the augmentation of the neural input to the muscle for the symmetrical smile.

Based on the aforementioned techniques, Biglioli et al. [7] developed a one-stage facial reanimation procedure with dual innervation, where the gracilis muscle was used as a free functional muscle flap innervated by the masseteric nerve, together with a cross-facial sural nerve graft. More exactly, the anterior branch of the obturator nerve is connected to the masseteric nerve. For the cross-facial sural nerve graft, a branch of the facial nerve from the healthy side is used for the proximal neurotomy, while the distal end of the sural nerve is connected end-to-side to the anterior obturator branch, after excising an epineural window. The end-to-side anastomosis of the cross-facial nerve graft is a neurotization technique that doesn't disrupt any regenerated axons from the masseteric nerve. Therefore, these regenerated

axons remain intact, even if the cross-facial nerve graft would fail to bring reinnervated axons to the gracilis muscle. In their cohort of 4 patients, all the patients were able to contract the muscle voluntarily at around 3.8 months postoperatively, while spontaneous flap activity was recorded around 7.2 months after the operation. The fact that the muscle also received reinnervated axons through the cross-facial nerve graft was confirmed by the motor potentials recorded with electromyography during stimulation of the contralateral facial nerve. The authors hypothesize that the axons passing through the cross-facial nerve graft also activate the masseteric nerve fibers, leading therefore to a favorable quantity of contraction during spontaneous smiling.

The masseter nerve is thought to provide a more powerful smile than the cross-facial nerve graft [59, 60]. The great axonal load, as well as the crossing of only one nerve connection support this statement. Even though this technique guarantees a shorter reinnervation time and a stronger muscle contraction, there is doubt that by the time the cross-facial nerve graft axons reach the muscle they still have free motor units to connect to. Based on this theory, Cardenas-Mejia et al. [52] described a variation of the double-innervation proposed by Biglioli [7]. The authors envisioned a two-stage reanimation procedure where a cross-facial nerve graft was connected to a branch of the healthy facial nerve and tunnelled to the paralyzed side in the first stage. In the second stage, the obturator nerve of the gracilis muscle was coapted in an end-to-end technique to the cross-facial nerve graft, while the masseteric nerve was connected end-to-side to the obturator nerve, about 1 cm away from the muscle. Their results showed an average of 70% motor unit recruitment, while clinically, all 9 patients achieved voluntary and spontaneous smile.

CONCLUSION

The strive for perfection will continue in facial reanimation surgery. Better understanding of the mechanisms and physiology of nerve regeneration will hopefully in the future enable the surgeon to produce an excellent surgical result in almost every case. The influence of proprioception of the transplanted muscle on functional outcomes is yet to be determined. Afferent sensory feed-back may also prove to be more important than previously thought in producing the required complex movement to enable the transplanted muscle to mimic the three-dimensional function of the normal facial musculature.

Brescia, Italy

ABSTRACT

Introduction of pediatric endoscopic sinus surgery (PESS) is relatively recent. Owing to the excellent outcomes of functional endoscopic sinus surgery observed in the adult population, in 1990s the development of suitable pediatric instruments and optics was encouraged. Moreover, improvements in technology and surgical techniques enabled pediatric otolaryngologists to progressively expand the surgical indications of endoscopic nasal approaches. Nowadays, PESS is routinely performed in children affected by sinonasal inflammation pathologies, anatomic malformations, benign expansible lesions, and lacrimal stenosis. Furthermore, this surgical management is favoring PESS over open approaches for CSF leak repair and other skull base disorders, including some neoplastic masses. However, specific considerations in PESS must be addressed. The major issues regard reduced nostril aperture and nasal fossae volume, and degree of sinus pneumatization. Herein, the authors describe this surgical technique and its main use in pediatric patients. Finally, the advantages of this less invasive surgery are described compared to traditional surgical treatments.

PEDIATRIC NASAL EMBRYOLOGY AND DEVELOPMENT

Thorough knowledge of nasal and paranasal sinuses anatomy is mandatory to achieve familiarity in endo-nasal endoscopic surgery. A major issue in the pediatric population concerning sinonasal anatomy is the variability according to age, stage of development, and

* Corresponding Author's Email: marco.berlucchi@tin.it; Fax: +390303996009.

pathology treated [1]. A key point in paranasal sinuses consists in the development of the maxillo- and ethmoido-turbinals by the 10th week of gestation from the lateral wall of the nasal capsule. Each of these ridges contribute to the formation of important anatomical structures and key landmarks in endoscopic surgery. The inferior turbinate develops from the inferior ridge, called maxillo-turbinal; 5 to 6 ridges develop superiorly and form the ethmoido-turbinals. The first ethmoido-turbinal forms the agger-nasi and uncinated process, and the second through fourth participate in the formation of portions of the bulla, middle and superior turbinate. The fifth and sixth ethmoido-turbinals degenerate or contribute to the supreme turbinate [1-3].

Two types of sinus pneumatization are recognized: “intramural” when confined to the nasal capsule (ethmoid primary pneumatization) and “extramural” when extended to the surrounding bones (ethmoid secondary pneumatization and other sinus development) [4]. In fact, whereas the maxillary, frontal, and sphenoid sinuses develop as extensions of the ethmoid (extra-nasal capsule development), ethmoid pneumatization starts within the nasal capsule as intra-capsular diverticular spaces (primary pneumatization) and progressively expanding beyond nasal capsule borders within the contiguous structures. Ethmoidal air cells develop by the 12th week of gestation and continue to grow up to early adolescence (generally around 12 years) [3-4].

The maxillary sinus is the first paranasal sinus to develop (by the 10th week) as a lateral bud from the ethmoidal infundibulum, between the first and second ethmoido-turbinals; at birth the sinus volume is small, but its diameter increases greatly in the first 8 years of life. During childhood and adolescence, the maxillary sinus continues to grow and, reaches an adult size by 16-18 years [5]. Frontal sinus development starts with migration of extramural anterior ethmoidal cells within the inferior aspect of the frontal bone during the 13th week of gestation. Thereafter, the anterior ethmoidal outpouching proceeds further between the frontal bone until about 20 years of age (can generally be seen on X-rays between 2 and 6 years). According to Terracol and Ardouin, the variable drainage pathway of the frontal sinus depends mostly on which ethmoidal cell the sinus developed (nasal, orbital or bullar groups) [4,6]. During the 4th month of gestation, the sphenoid sinus develops as an “extramural” extension of posterior ethmoidal cells from the sphenoethmoidal recess, with a posterior directed gradual extension starting from the antero-inferior wall, proceeding to the floor and then to the planum sphenoidale and anterior sellar wall. A varying degree of sellar floor pneumatization is reached in the majority of patients by age 7; extension beyond the posterior sellar wall, when present, rarely occurs before age 12 [7]. Absence or underdevelopment of the frontal and sphenoid sinuses is typical of Down and Apert’s syndromes. The skull base derives almost entirely from the chondrocranium (cartilaginous neurocranium) and starts its development at the 4th week of gestation. The basicranium grows slower than the cranial vault. The anterior skull base is cartilaginous at birth, with a progressive ossification process that becomes evident by 4 months of age. Between the ages of 2 and 4 the anterior cranial fossa reaches an adult conformation, with the definitive closure of the spheno-ethmoidal and ethmoido-frontal sutures by adolescence. Anterior displacement of the anterior skull base, frontal bone, and sinus occur during the first years of life secondary to development of the frontal lobe and nasomaxillary complex [8].

Pediatric ENT surgeons must always keep in mind that any surgical procedure in this anatomical region can potentially affect normal development of the craniofacial complex. Extensive procedures on the skull base demands a thorough knowledge of sinonasal and skull base growth centers in order to avoid a major impact on their key role.

NASAL ENDOSCOPY AND PEDIATRIC NASAL ENDOSCOPIC ANATOMY

In-office diagnostic nasal endoscopy is generally performed with patients placed in either a sitting position or kept in the arms of a nurse or parent. The application of cottons soaked with decongestants and local anesthetics in the nasal cavity is generally preferable to increase compliance and space of the nasal cavity. When the use of cottons is not tolerated or in patients younger than 36 months, a local anesthetic can be sprayed in the nasal cavity. In neonates, topical drugs are not generally utilized. Before starting the endoscopy, the child should be informed about the procedure in the attempt to get better collaboration. Four-mm rigid endoscopes are generally reserved for compliant patients older than 8 years; 2.7 and 3 mm rigid endoscopes ensure the same visual quality with better performance in small nasal fossae. Flexible endoscopes, despite the lower visual quality, must be used in non-compliant patients because of their nearly negligible traumatic potential. After removal of cottons and application of anti-fog products on the endoscopic lens, the endoscope is delicately inserted into the nasal fossa. Endoscopic access through the nostril in the first 6 years of life can be difficult because of the significantly narrower aperture, and can pose a major issue during surgical procedures that require the simultaneous use of two instruments. Diagnostic endoscopy is a standardized procedure that is generally performed as follows. First, it starts with the inspection of the nasal fossa floor, nasal septum, inferior nasal turbinate, and inferior meatus; it then proceeds along the floor of the nasal cavity to observe the choanal aperture, nasopharynx, Eustachian tube orifices, and torus tubarius. At this point, the endoscope is directed superiorly and proceeding backwards to assess the sphenoethmoidal recess, middle turbinate, and middle meatus. The uncinate process, bulla ethmoidalis, and iatus semilunaris are generally easily assessable. Finally, anterior to the middle turbinate, the endoscope is rotated superiorly to evaluate the olfactory fossa. Complications are rare, and the most common is nasal bleeding, which is often self-limiting. Parents should be informed to not let their children drink or eat for 20 minutes after the procedure because of partial laryngeal anesthesia from nasal local anesthesia.

Endoscopy plays a major role as a diagnostic tool in the evaluation of the nasal anatomy and functional status by assessing the mucosa, presence of pathologic secretions and their origin, inspection of adenoid hypertrophy, and diagnosis of nasal masses (polyps, congenital malformations, tumors, etc.). In addition, thanks to its high benefit/cost ratio, it is commonly used to evaluate response to medical treatment and for surgical follow-up.

Surgeon operates holding in his hands surgical instrumentations and nasal rigid endoscope connected to camera. The surgeon can check the surgical procedure on the monitor sited in front of him (A). Close up view of nasal endoscope (arrow) and surgical instrumentation (white arrowhead), both inserted into nasal fossa.

PEDIATRIC ENDOSCOPIC SINUS SURGERY

Pediatric endoscopic sinus surgery (PESS) (Figure 1A, B) is performed for several sinonasal disorders ranging from inflammatory diseases to malignant tumors. Herein, the main sinonasal pathologies treated by nasal endoscopic surgical approaches are presented.

Inferior Turbinate Hypertrophy

Inferior turbinate hypertrophy can be either congenital or acquired. The former is rare, whereas the latter is usually due to septal deviation, allergic rhinitis, or gastroesophageal reflux disease [9-10]. The primary presenting symptom is nasal obstruction occasionally associated with seromucosal rhinorrhea, itching, and sneezing. Moreover, chronic nasal obstruction can modify the normal function of the Eustachian tube causing effusion in the middle ear [11]. Diagnosis is made by nasal endoscopy. Rhinomanometry in basal conditions and after nasal decongestion can be useful in selected cases. Medical therapy is usually effective and consists of regular saline irrigations and the application of topical steroids for at least 3 weeks. Association of topical steroids with an anti-histamine is a valid alternative for patients with allergies. Surgery is reserved for hypertrophy resistant to medical therapy and, in pediatric patients, is generally performed under general anesthesia.

Adenoid Hypertrophy

Adenoid hypertrophy represents the most common cause of nasal obstruction in the pediatric population, and is generally diagnosed in the first 6 years of life. The most commonly observed manifestations are bilateral nasal obstruction, snoring, mouth breathing,

rhinorrhea, hyponasal speech, and cough. Clinical history commonly shows recurrent episodes of acute otitis media, persistent effusive otitis and/or chronic or recurrent rhinosinusitis [12]. Adenoid hypertrophy may play a major role in pediatric chronic rhinosinusitis, working as a reservoir for pathological bacteria [13-15]. For this reason, adenoidectomy with or without antral irrigation and balloon sinus dilation can be considered as first-line treatment when maximal medical therapy fails. Adenoid hypertrophy may also present with episodes of sleep apnea and, albeit rarely, affect the cardiovascular system (cor pulmonale in extreme cases). Nasal endoscopy is the gold standard diagnostic procedure for adenoid hypertrophy, evaluating size, intrachanal extension, residual choanal lumen, and anatomical relationships with the Eustachian tube orifice. Adenoids (Figure 2) appear as a lobulated, pinkish, pyramid-like shaped aggregations of lymphoid tissue with the apex pointed toward the nasal septum and the base at the level of the superior and posterior nasopharyngeal walls. Many surgical options have been developed for treatment of adenoid hypertrophy. In our opinion, the use of adenotome or microdebrider under endoscopic control with a 70° angle optic rigid scope represents the best surgical option for removal of adenoids.

Sinonasal Polyposis

Except for antrochoanal polyps, polyposis is quite rare in the pediatric population [16] and when bilateral should raise concern for a potential diagnosis of cystic fibrosis or fungal allergic rhinosinusitis. Even if some predisposing factors are well known (i.e., hereditary, allergies, asthma and aspirin sensitivity), the etiology of sinonasal polyposis is still debated. Sinonasal polyposis can be classified into 5 categories [17]: 1. antrochoanal polyps; 2. choanal polyps; 3. polyposis associated with chronic rhinosinusitis (non-eosinophilic dominated); 4. polyposis associated with chronic rhinosinusitis (eosinophilic dominated); 5. polyposis associated with specific illnesses (asthma, cystic fibrosis, primary ciliary dyskinesia, etc.)

Figure 2. At nasal endoscopy, adenoid hypertrophy (asterisk) obstructing totally the posterior choanae.

Children affected by this disorder report hypo/anosmia, nasal obstruction, rhinorrhea, and sometimes headache or facial pressure [16]. Diagnosis is easily confirmed by nasal endoscopy. Polyps (Figure 3) show a characteristic edematous and translucent appearance

(closely resembling a grape) and generally originate from the middle meatus or the olfactory region. Computed tomography (CT) scan is the gold standard diagnostic technique, defining the exact extension of disease and allowing for detailed study of sinonasal anatomy in the preoperative setting [16].

Figure 3. Nasal polyps obstructing completely right nasal fossa.

Medical therapy is usually effective and is managed through saline irrigations and the application of topical steroids for at least 4 weeks. Allergic patients may benefit more from a combination of topical steroids and anti-histamine drugs. When symptoms are not tolerated and polyposis proves to be resistant to medical therapy, surgery is offered to the patient. In the pediatric population, polypectomy is usually performed under general anesthesia. After the application of cottons soaked with decongestants into the nasal cavity 10 minutes before starting surgery, a solution of local anesthetic and epinephrine is injected at the level of the polyp pedicle, which is then stripped with Weil forceps, or more commonly removed by micro-debrider. When planning a polypectomy, it is recommended to define the surgical strategy according to the necessity to correct anatomic anomalies that have might favored the formation of polyps.

Antrochoanal polyp (ACP) is a peculiar form of sinonasal polypoid formation, more frequently observed in infants, where it is observed in almost one-third of cases of polyposis [18-21]. ACP are usually unilateral and has a male prevalence (M:F = 2.1:1). They originate inside the maxillary sinus, from one of the intramural Tonrwaladt's cysts within sinus walls [22-23]. As it grows, it first occupies the maxillary sinus volume, and then protrudes through the natural or accessory maxillary ostium into the nasal cavity towards the choanal aperture. ACP generally shows a cystic composition in its intra-maxillary portion and a solid composition in the emerging portion within the nasal fossa. Clinical presentation depends on local extension. Patients generally complain of unilateral nasal obstruction, occasional bleeding, rhinorrhea, and foreign body sensation [24-25]. Bilateral symptoms are typical of ACPs with large involvement of the nasopharyngeal lumen or when ACP is bilateral. Dysphagia, dyspnea, and pharyngeal sensation of foreign bodies may be reported by extremely advanced cases. Diagnosis can be easily confirmed by endoscopy. A bright-white mass protruding from the middle meatus and occupies the nasal cavity with a variable

posterior extension toward the nasopharynx. CT (Figure 4) offers details of sinonasal anatomy and disease extension. MRI is not routinely performed.

Acute and Chronic Rhinosinusitis

Rhinosinusitis is defined as an inflammatory condition of the sinonasal tract, characterized by the presence of at least two of the following symptoms: nasal obstruction, hypo/anosmia, cough, pain on pressure of tender spots, facial pain and/or headache, rhinorrhea, and postnasal drip [26]. Diagnosis is generally confirmed by endoscopy, demonstrating diffuse mucosal inflammation, turbinate congestion, and pathologic nasal discharge (more commonly coming from the middle meatus).

Based on duration of symptoms, rhinosinusitis can be distinguished as:

1. acute rhinosinusitis, when symptoms lasts less than 12 weeks;
2. chronic rhinosinusitis, when symptoms lasts continuously at least 12 weeks; and
3. recurrent chronic rhinosinusitis, when multiple acute episodes occur with complete resolution of each within 12 weeks.

The association of chronic rhinosinusitis with nasal polyposis is far less common in the pediatric age compared to adult population. Recurrent/chronic rhinosinusitis and the concomitant presence of bilateral polyposis should raise concern for immunodeficiency and primary ciliary disorders. CT scan is usually reserved for chronic rhinosinusitis when endoscopy is not sufficient to make differential diagnosis and/or surgical treatment is necessary. Because of the underdevelopment of frontal and sphenoid sinuses in the first years of life, CT scan often shows involvement of maxillary and ethmoid sinuses. The Lund-Mackay score is a reliable and highly predictive model used for diagnosis of chronic rhinosinusitis based on CT findings [27]. MRI is mandatory when clinical presentation raises suspicion for severe forms or orbital (Figure 5) or intracranial complications.

Figure 4. At CT scan, Antrochoanal polyp fills the right maxillary sinus growing the natural ostium (arrow) into the middle meatus to the choana (asterisk).

Figure 5. Coronal MRI view of the left extraconal orbital lesion (asterisk) associated with displacement of the orbital globe.

Differential diagnosis should exclude viral or allergic rhinitis and adenoid infection or hypertrophy. Once diagnosis is made, the ENT specialist must always take into account concurrent disorders that may coexist with chronic rhinosinusitis: adenoid hypertrophy, immunodeficiency, asthma, cystic fibrosis, allergy, ciliary dyskinesia, and gastroesophageal reflux disease. Accurate anamnesis and close collaboration with pediatrics, pulmonologists, and immunologists is therefore recommended.

Pathogens most commonly isolated in acute rhinosinusitis are those generally responsible for acute bacterial upper airway infections such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catharralis*. However, *Staphylococcus aureus* and anaerobes can be occasionally found [28]. Origin of purulent discharge can be assessed through endoscopy, and nasal samples for cultures can be easily taken directly from the involved meatus. At first presentation, microbiological cultures are not mandatory since the success rate of empiric antibiotic therapy is satisfactory. When patients fail to improve despite medical therapy within 72 hours or a second episode recurs within 2 weeks, cultures are necessary to guide antibiotic therapy. Cultures are also mandatory in any case of rhinosinusitis with severe presentation or in immunocompromised patients [29-30].

Medical therapy is the first treatment of choice for chronic rhinosinusitis. The European Position Paper on Rhinosinusitis and Nasal Polyps [26] suggests an algorithm for treatment of pediatric chronic rhinosinusitis based on presentation. Mild symptoms may be managed with nasal saline irrigation and application of nasal topical steroid puff. The use of oral antibiotics is reserved for persistent symptoms or moderate to severe symptoms. Antibiotic therapy is generally empiric (e.g., amoxicillin/clavulanate) and requires one or two courses. When medical therapy fails to control symptoms of chronic rhinosinusitis and acute infection exacerbates, intranasal samples of nasal discharge should be taken and antibiotic chosen according to the pathogens isolated. When maximal medical therapy fails, surgical therapy must be considered: adenoidectomy with or without antral irrigation and balloon sinus dilation, and PESS are the most commonly performed surgical procedures.

PESS represents the surgical treatment of choice for complicated rhinosinusitis or when associated with systemic conditions (i.e., cystic fibrosis). Because of potential harm to

sinonasal and facial growth centers, it is recommended to adopt a conservative approach aimed to restore nasal fossa patency by polypectomy, correction of turbinate hypertrophy or concha bullosa, anterior ethmoidectomy, and maxillary antrostomy. PESS is always performed under general anesthesia and requires the use of rigid endoscopes of different angles (0°, 30°, 45°, 70°) and size (4 mm, 3 mm, 2.7 mm diameter). Generally, the application of cottons soaked with decongestants in the nasal cavity 10 minutes before starting surgery increases nasal fossae volume. A solution of 1% mepivacaine chlorohydrate and 1:200,000 epinephrine is then injected in the submucosa at the roof of the middle turbinate and uncinate process. With a small seeker, the posterior aspect of uncinate process and main ostium of maxillary sinus are probed before proceeding with uncinectomy. In order to be as conservative as possible, the uncinectomy is partial and the upper third is conserved. Natural ostium of maxillary sinus is then widened both inferiorly and posteriorly. Once the uncinate process has been removed, the anterior wall of the bulla ethmoidalis is visible and is opened using a debrider or a Weil forceps. Following this, the opening of basal lamella medially and inferiorly is performed to give access for posterior ethmoidectomy. The aperture of the sphenoid sinus is achieved at an infero-medial angle because of the close relationship on the lateral side with optic nerve and internal carotid artery. Just below the sphenoid sinus aperture runs the posterior septal branch of sphenopalatine artery, which should be preserved if a Hadad-Bassagasteguy flap [31] for skull base reconstruction is planned. Sphenoid sinusotomy can also be effectively performed through a trans-nasal or a trans-septal corridor. Frontal sinusotomy is rarely required as the frontal sinuses are usually underdeveloped until late childhood. When necessary, this procedure should be performed by pediatric ENT surgeons with expertise in sinonasal and skull base surgery, even if it is generally sufficient to remove agger nasi cells after anterior ethmoidectomy in order to expose the frontal recess, where a sinusotomy can be easily performed using angle circular-biting forceps.

Adenoidectomy with intranasal irrigation and balloon sinuplasty represent a surgical alternative to PESS, especially for children without complicated rhinosinusitis [32-33]. The role of adenoids in chronic rhinosinusitis in children is under debate. The long-term benefit some patients with chronic rhinosinusitis gain from adenoidectomy may suggest a major role of adenoids in maintaining sinonasal chronic infection [13], [14-15] although a definitive conclusion cannot be established with current evidence. In chronic rhinosinusitis, adenoidectomy is generally performed along with maxillary antral irrigation. Balloon sinuplasty may be performed to increase the definitive outcome. However, its real impact on sinonasal restoration is yet to be determined.

Complications and Quality of Life

PESS is considered a safe and effective treatment for pediatric chronic rhinosinusitis. The success rate, defined as increased quality of life, reduced symptoms and/or willingness to suggest PESS to other patients, varies from 76% to 89% [27,34-35]. Patients affected by chronic rhinosinusitis with or without cystic fibrosis, eligible for PESS, reported an impaired general quality of life prior to surgery. Dedicated questionnaires were submitted to analyze specific quality of life after PESS for these patients, showing a net improvement after 1-3 months [36].

Reported complications from PESS range between 0.6% - 1.4% [27,34,37]. Although rare, PESS may result in major complications, including orbital damage, skull base lesion with subsequent CSF leak, and meningitis, requiring prompt intervention. Minor complications (i.e., minor bleeding, synechiae, local infection) are usually treated conservatively. The low overall risk of readmission, reoperation and complication rates were also confirmed by a recent study, with reported rates of 4.5%, 2.6%, and 3.0%, respectively. In this study, independent factors associated with an increased risk of postoperative adverse events were urgent/emergent procedures and presence of bleeding disorders. Age < 3 years was an independent risk factor only for bleeding requiring transfusion [38].

Mucocele

Mucocele is a benign, cyst-like, locally expansive paranasal sinus mass consisting of a collection of aseptic mucus, and products of mucosal debris, lined by respiratory mucosa, that develops within a paranasal sinus [39,40]. A mucocele grows slowly and expands by eroding the surrounding bony walls as a consequence of ostium blockage. The obstruction can result from congenital anomalies, adhesences from chronic rhinosinusitis, previous radiotherapy and/or surgical treatment, trauma, and sinonasal neoplasms [41]. Recognized predisposing factors are congenital illnesses such as cystic fibrosis and primary ciliary dyskinesia. Mucoceles occur rarely in the pediatric age, and most cases described were associated with the abovementioned congenital conditions [42-44]. The most common site of origin is the frontal sinus, where it occurs in 60% of cases, followed by the ethmoid labyrinth and maxillary sinus with 30% and less than 10% of cases, respectively. Few cases are localized in the sphenoid sinus [45]. The higher incidence of mucoceles in the frontal sinus seems to be related to anatomical complexity of the frontal recessal [46]. Mucoceles are almost always monolateral, and no gender prevalence has been observed. Clinical presentation is dependent on localization, but is generally characterized by nasal obstruction, headache or facial pain, rhinorrhea, cheek swelling, allodynia or dental pain, and local hypo/anesthesia. When a frontal mucocele grows enough to involve the orbital content, periorbital pain, edema, proptosis, diplopia, blurred vision, and sudden vision loss can occur [40,47]. Whenever erosion of the anterior or posterior wall of the frontal sinus is present, a Pott's puffy tumor or neurological symptoms may be evident. Diagnosis is based on signs and symptoms, nasal endoscopic evaluation, and imaging. Nasal endoscopy is generally silent during the intra-sinusal phase, whereas, during subsequent expansion of the mucocele, alterations of the bony walls of the paranasal sinus may be evident. Advanced maxillary mucocele may cause medialization of the middle turbinate, anterior dislocation of the uncinate process (Figure 6), and bulging of the agger nasi cells. Submucosal remodeling or bulging of the sphenoethmoid recess or posterior ethmoid, on the other hand, is more typical of high-volume sphenoidal mucoceles. In frontal mucoceles, endoscopic examination is usually negative, since the lesion expands inferiorly to involve the agger nasi [48]. CT scan shows an homogenous lesion that completely occupies the involved sinus with smooth clear-cut margins of bone erosion of its walls, giving details on the origin, extension of disease, entity of bony erosion, and hyperostotic changes (Figure 7). MRI is usually reserved for mucoceles secondary to sinonasal expansive tumors.

Figure 6. Endoscopic view of the anterior dislocation of the uncinate process (asterisk) and medialization of the middle turbinate (arrow).

Figure 7. Axial CT scan, lesion involves completely the maxillary sinus bilaterally and erosion of the medial bone walls (arrows) is evident.

Naso-Lacrimal Duct Congenital Disorders

Naso-lacrimal duct obstruction (NLDO) in the newborn and infants is usually congenital, secondary to a defect of its canalization during embryogenesis. This defect typically presents at the level of Hasner valve. Causes of this disorder include persistence of a membranous diaphragm, bony stricture, or ab-extrinsico closure from edematous nasal mucosa. At birth, the persistence of a membrane at the Hasner valve can be found in 20 -30% of newborns. However, in many cases canalization occurs spontaneously hereafter [53]. Children affected by NLDO show persistent epiphora and an increased risk of lacrimal system infection. Crusting of the ipsilateral medial canthus is commonly observed. Diagnostic work-up generally includes nasal endoscopy and ophthalmologic evaluation. Dacryocystography (Figure 8) is commonly performed to confirm diagnosis and localize the site of obstruction [54]. When dacryocystorhinostomy (DCR) is planned, presurgical CT scan of the sinus is mandatory to evaluate sinus anatomy.

Treatment of this disorder includes conservative and non-conservative procedures. When conservative approaches such as lacrimal massage, probing and irrigation of lacrimal system, balloon dacryoplasty, and nasolacrimal duct intubation fail, DCR is mandatory. Despite the optimal success rate and diffusion of external approaches, endoscopic-DCR is encouraged because of the far lower incidence of complications and recovery time and because it is less invasive than external surgery. Use of a nasolacrimal stent is debated, since it might elicit local inflammatory response and granulation, increasing the risk of re-stenosis [57,58]. Known risk factors for surgical failure are pre-saccal obstruction and presence of craniofacial anomalies. Major complications following endoscopic DCR are exceedingly rare [52,54-56]. Minor complications include bleeding, synechiae, and eye itchiness. A new promising and more conservative endoscopic-assisted procedure has been reported. After inspection of the inferior meatus, the valve of Hasner is incised and the nasolacrimal duct is irrigated [59].

Figure 8. Dacryocystography shows obstruction of the lacrimal system at inferior third of the lacrimal sac (arrow).

Naso-lacrimal duct cysts (NLDC) (Figure 9) are congenital cystic dilation of the distal portion of the nasolacrimal duct secondary to failure of the Hasner membrane to canalize. It is a rare condition, most commonly symptomatic at birth or within few weeks of age [60]. It is more commonly observed in females. Clinical presentation depends on extension and laterality. Monolateral NLDCs typically present as ipsilateral persistent epiphora, recurrent dacryocystitis, and nasal obstruction, whereas bilateral NLDCs may cause acute respiratory distress at birth because of bilateral nasal obstruction. Susceptibility to aspiration and feeding difficulties may accompany bilateral NLDCs [61]. The evidence of a grayish-blue cystic mass in the inferior meatus on nasal endoscopy confirms diagnosis. CT scan can further confirm diagnosis showing a cystic formation at the level of Hasner's valve in the lateral wall of the inferior meatus, with progressive dilation of nasolacrimal duct and lacrimal sac. Surgical intervention is indicated for symptomatic patients, since spontaneous canalization occurs in most patients within 9 months after birth. Under general anesthesia, the cyst is endoscopically incised, drained, and marsupialized into the inferior meatus [62-63].

Congenital Choanal Atresia

Congenital choanal atresia (CCA) is defined as the congenital pathological closure of the posterior choanae, either mono- or bilateral, by a diaphragm of membranous, bony, or mixed tissue. CCA is the most common congenital malformation in the sinonasal tract, with an incidence of 1 in 5000-9000 live births, with a prevalence for the female gender and the right side (both with a ratio of 2:1) [64,65]. The pathogenesis of CCA is still debated. Persistence of the bucco-pharyngeal membrane, naso-buccal membrane of Hochstetter, misdirection of neural crest cell migration, and abnormal location of mesoderm are the most accepted theories [66,67]. CCA is an isolated finding in 50% of cases, while in the remaining is due to syndromic conditions. CHARGE (Coloboma, Heart disease, Atresia choanae, Retarded growth, Genital anomalies, Ear anomalies), Di George, Treacher Collins syndromes and Blackfan-Diamond anemia are the most important in this regard [67]. Choanal narrowing is caused by the presence of a pathologic diaphragm, extended from the floor of the sphenoid bone to the horizontal process of the palatine bone, and from the vomer to the medial pterygoid plate. Since the condition is mainly secondary to bony malformation of vomer and sphenoid bone, in almost all cases the diaphragm has a mixed (70%) or bony (30%) structure, while a pure membranous occlusion is extremely rare [68-70].

CCA is unilateral in two-thirds of cases and bilateral in the remaining. Bilateral CCA usually presents at birth as an airway emergency, since newborns show an obligate nasal ventilation. Severe respiratory distress, paradoxical cyanosis and stridor are the most commonly observed symptoms [64]. Differential diagnosis includes other sinonasal congenital malformations (midnasal or pyriform aperture stenosis), bilateral nasolacrimal duct cysts, septal deviation, nasopharyngeal wall collapse and reflux, and congenital sinonasal lesions (e.g., teratoma) [71]. In these cases, prompt intervention to secure airway is mandatory, and pediatric ENT surgeons must be prepared for tracheostomy in selected cases. Unilateral CCA usually shows a delayed presentation (5-24 months or even after), with symptoms of unilateral nasal obstruction and ipsilateral otitis media on occasion. Differential diagnosis includes septal deviation, nasal foreign bodies, inferior turbinate hypertrophy, antrochoanal polyp, and expansive sinonasal benign or malignant lesions [64].

Diagnosis can be easily confirmed by observing fogging on a cold metal speculum positioned at the nasal pyriform aperture [64]. For differential diagnosis with pyriform aperture stenosis, a catheter is inserted into the nasal cavity: if it passes through the nasal cavity, but is blocked more posteriorly, CCA is confirmed. Nasal endoscopy and CT (Figure 10) represent the gold standard for definitive diagnosis. Nasal endoscopy shows a complete uni- or bilateral choanal occlusion, usually associated with abundant mucous secretions. CT allows evaluation of the bony details of the CCA and other craniofacial malformations that can accompany choanal atresia in syndromic cases. In order to exclude CCA as part of a syndromic condition, thorough diagnostic work-up, including evaluation of craniofacial malformations, muscle tone, and airway assessment, is usually recommended [64].

Therapeutic strategies are planned based on type, grade of stenosis, and associated conditions. While bilateral CCA requires prompt intervention aimed to secure the airway and stabilize ventilation, surgical planning for unilateral atresia might be postponed after the first years of life in order to increase the rate of success. The first surgical approaches introduced were transnasal puncture and transpalatal repair, but were progressively abandoned in favor of transnasal endoscopic choanal plasty [72,73]. In order to maximize the chance of success

and reduce the rate of restenosis, medial choanal enlargement over lateral extensive drilling, and protection of exposed bone with local mucosal flap are encouraged [74].

Figure 9. At endoscopic evaluation, a naso-lacrimal duct cyst (asterisk) is observed.

Figure 10. CT-scan shows left choanal atresia (white arrow).

A metanalysis published in 2008 reported that endoscopic choanal plasty had a success rate of 85.3%, although criteria for definition of failure varied widely among the individual studies considered [72]. Risk of restenosis is mainly associated with bilateral CCA, CHARGE syndrome, and age and weight at the time of surgery [75]. Recent data show a higher risk of failure with the employment of choanal stents, secondary to granulation and inflammatory reactions that may locally cause [76,77]. For this reason, their use is discouraged. Application of topical steroids and accurate endoscopic toilette of the nasal cavities have been reported as fundamental precautions in reducing the risk of re-intervention.

Nasal Dermoids

Nasal congenital midline lesions, consisting of nasal dermoids, gliomas, and encephaloceles, are rare developmental malformations with an estimated incidence of

1:3000 - 1:40,000 births [78,79]. Nasal dermoids (ND) are defined as frontonasal inclusion cystic masses, sometimes associated with sinus opening. Males are slightly more affected. NDs may associate with other congenital malformations (5 - 41%), such as external ear anomalies, cleft lip and palate, hypertelorism [80]. Foramen caecum plays a key role in the pathogenesis of these congenital anomalies. It is a transient skull base corridor, anterior to the crista galli, that forms from the third week of gestation. Through the foramen caecum, the dura protrudes towards the prenasal space, located posteriorly to the nasal bone, where the ectoderm is apposed. As the foramen caecum regresses spontaneously during the eighth week of gestation, the dura retracts back into the intracranial space. Nasal dermoids typically form from ectodermal and mesodermal tissues entrapped along the dural descent pathway towards the prenasal space [81].

Histologic examination confirms the presence of ectodermal and mesodermal elements (i.e., hair, keratin, sweat, and sebaceous glands). Lack of the endodermal component differentiates them from teratoma. Unlike encephaloceles and gliomas, NDs do not present glial elements. Generally, clinical presentation is peculiar. A dimple, fistula or cystic lesion can present anywhere along the embryologic midline line, from the nasal tip into the skull base, with the rhinion as the most common location. Although a rare finding, hair protruding through the midline lesion is pathognomonic for nasal dermoid. When a midline external lesion presents protruding hair, this is pathognomonic for nasal dermoids. A widened nasal bridge, intermittent sebaceous discharge, and recurrent infections are commonly observed. Unlike encephaloceles, NDs do not transilluminate and do not expand with crying. NDs may have an intracranial extension in 4% 45% of cases, with a potential for recurrent meningitis (caused by skin flora bacteria) [80].

Diagnostic work-up includes nasal endoscopy and radiological imaging, and should be aimed at identifying the location and size of ND, indirect or direct signs of intracranial extension, nasal anatomy, and associated malformations. Indirect signs of intracranial extension are well-established with CT and include bifid crista galli, enlarged foramen caecum, and cribriform plate anomalies [82]. If intracranial tract is suspected, contrast-enhanced MRI is recommended.

Surgical treatment is mandatory since progressive enlargement of NDs can cause craniofacial deformities, recurrent infections, meningitis, and brain abscess. The surgical strategy should obtain radical removal, allow proper skull base reconstruction, with optimal cosmetic outcomes [83].

Conservative treatment, such as curettage, drainage, and aspiration are not recommended, because of the high risk of recurrence [83]. Different surgical strategies have been proposed according to the type of ND and its extension, with external rhinoplasty incision as the most widely adopted. When NDs show intracranial extension, coronal incision and frontal craniotomy are generally required. Although external approaches are considered safe and effective [84-87], efforts have been made to introduce endoscopic-assisted transnasal excision for intracranial NDs [88-89].

Encephalocele

Encephaloceles are sac-like herniations of intracranial content caused by a skull base defect [90]. They are called meningoceles when formed only by meningeal linings and CSF,

and meningo-encephaloceles when brain tissue is also included. Encephaloceles form secondary to failure of proper neural tube closure. No gender predominance has been reported. The incidence is higher in Asia, with a reported incidence of 1 in 6000 births [91]. Low levels of maternal folic acid during first weeks of development may be a major risk factor. Encephaloceles typically present as smooth, white-bluish, pulsatile lesions, increasing in volume with crying or on jugular vein compression (Furstenberg sign) [90]. If left untreated, encephaloceles can cause recurrent meningitis and epilepsy. Depending on their localization, encephaloceles are classified into 3 major classes: *sincipital*, *basal*, *occipital*.

Sincipital encephaloceles are further classified as *naso-frontal*, *naso-ethmoidal*, and *naso-orbital*. *Nasofrontal* encephaloceles develop through a defect between nasal and frontal bones, presenting as a protruding mass in the glabellar region and causing inferior displacement of nasal pyramid and lateral displacement of the eyes (telecanthus). *Nasoethmoidal* encephaloceles protrude through a patent foramen caecum towards the prenasal space, where junction of nasal cartilages and bones is located (rhinion). Typical presentation is a mass on the nasal dorsum causing a superior displacement of nasal bones and inferior displacement of alar cartilages. If an encephalocele protrudes through a patent foramen caecum and laterally extends through a defect in the medial orbital wall, then a *naso-orbital* encephalocele forms, causing ipsilateral proptosis, visual impairment, epiphora, and recurrent dacryocystitis. *Basal* encephaloceles originate more posteriorly, between the cribriform plate and the middle skull base. They are further classified as *transethmoidal*, *sphenoethmoidal*, *transsphenoidal*, and *sphenorbital*. *Transethmoidal* and *sphenoethmoidal* encephaloceles present as an endo-nasal protruding mass, causing nasal obstruction and orbital displacement (hypertelorism). They occur secondary to a defect in the cribriform plate or at sphenoethmoidal junction, respectively. *Trans-sphenoidal* encephaloceles develop secondary to a persistent craniopharyngeal canal, protruding into nasopharynx, causing nasal obstruction and affecting swallowing. Trans-sphenoidal encephaloceles are typically associated with cleft palate defects. *Spheno-orbital* encephaloceles expand toward the spheno-palatine fossa, passing through the superior and inferior orbital fissures. Ipsilateral proptosis and visual impairment with no visible masses is the typical presentation. Finally, *occipital* encephaloceles occur secondary to a defect in the posterior cranial fossa.

The neural tissue in meningo-encephaloceles was initially considered dysplastic and non-functioning, but since functioning brain has been found in some occipital and trans-sphenoidal encephaloceles, this concept has been recently revised [90]. The presence of ependymal tissue on histologic examination is pathognomonic [92]. Diagnosis of an endo-nasal protruding encephalocele is made by nasal endoscopy and CT and/or MRI. Contrast-enhanced MR allows to identify the composition of the encephalocele (meninges with or without brain tissue), and also provides details on skull base defects and possible associated malformations. In order to obtain the best outcomes, prompt surgical intervention within the first months of life is advisable. Traditionally, small lesions could be managed endoscopically, while external craniotomic approaches were reserved for larger lesions.

Gliomas

Nasal gliomas (NG) are a rare benign developmental disorder, composed by heterotopic glial tissue, sequestered outside the cranium secondary to premature and abnormal skull base

closure (e.g., foramen caecum) [94-96]. For this reason, gliomas lack a patent communication with the brain (in contrast to encephalocele), and therefore do not transilluminate and do not show a change in size with straining, crying, or jugular vein compression (negative Furstenberg sign) [90]. However, a fibrous attachment to the dura can be identified in a minority of cases. NGs are classified into *extranasal* (60% of cases), *intranasal* (30% of cases), and *mixed* (10% of cases). *Extranasal* NGs present as a firm, smooth mass, external to the nasal bones and cavities (more commonly at the glabella). *Intranasal* NGs lie within the nasal cavity (more commonly from nasal lateral wall close to the middle turbinate) and can protrude through the ipsilateral nostril, causing nasal obstruction. Further extension to adjacent sinuses is not common. *Mixed* NGs show a typical dumbbell shape with a connecting band between the extra- and intra-nasal components. NGs are present at birth, although clinical presentation occurs typically between 5 and 10 years of age and may include: nasal obstruction, epistaxis, CSF rhinorrhea, broadening of the nasal bridge, hypertelorism, and epiphora secondary to nasolacrimal duct stenosis [96-98]. The intranasal components present as a non-pulsatile polypoid mass with a gray-reddish-purple color on nasal endoscopy. CT and contrast-enhanced MR are mandatory for diagnosis, in order to study nasal anatomy, bony structures, skull base attachment, and possible associated malformations. Extranasal gliomas generally require external surgical access that allows possible exploration of the skull base, with external rhinoplasty as the most commonly adopted approach. Intranasal gliomas are generally successfully treated with an endoscopic approach. In patients with fibrous attachment to dural layer, it is recommended to follow its entire course, in order to be radical and exclude intracranial extension. If required, endoscopic skull base reconstruction can be performed with synthetic, allogeneic, autologous tissue and/or local flaps [93].

Cerebrospinal Fluid Leak

Cerebrospinal fluid (CSF) leak occurs when there is an abnormal communication between the subarachnoid space and the sinonasal tract and/or the ear cavity, through a breach of the skull base and underlying meninges [90]. CSF leaks are classified as *non-traumatic* (with high or normal CSF pressure) and *traumatic* (accidental and iatrogenic) [99]. Traumatic skull base lesions are the most common cause of CSF leak: 80% secondary to craniofacial trauma and 16% secondary to sinonasal or skull base surgery [100]. Spontaneous CSF leak may be caused by congenital defects (potentially associated with encephaloceles, large arachnoid granulation cysts), skull base erosion by malignant tumors, or indirectly by increasing CSF pressure (i.e., aqueductal stenosis). The most common locations for spontaneous CSF fistula are the cribriform plate, sphenoid sinus, and pterygoid recess. Unilateral or bilateral watery rhinorrhea (rhinoliquorrhea), which is exacerbated when the patient bends forward, is the most typical presentation. Clinical manifestation of CSF leak may also include salty or sweet taste, recurrent meningitis, and signs of CSF hypertension such as headache, vomit, and papilla edema [90]. The “reservoir sign” is suggestive for sphenoid CSF fistula. In a recumbent position, CSF accumulates within the sphenoid sinus, until the patient resumes an erect position and sudden abundant watery rhinorrhea occurs [101].

Laboratory test on watery rhinorrhea can confirm the CSF leak by demonstrating the presence of beta-2 transferrin or beta-trace protein, polypeptides exclusively produced by the

CNS. Fluorescein test consists in the intra-techal administration of fluorescent dye solution, allowing the surgeon to localize the specific site of the leak. Fluorescein test can be used for pre-operative diagnosis, have a pre-operative diagnostic role, or an intra-operative role in guiding surgery. Contrast-enhanced CT and MR are recommended to study skull base anatomy, extension of the CSF leak, and possible associated disorders [90,102-103].

Reconstruction of Pediatric Skull Base Defects

Endoscopic skull base reconstruction can be performed with synthetic, allogeneic, autologous tissue and/or vascularized pedicled flaps. For large skull base defects, especially with moderate-high CSF pressure (as in the middle cranial fossa), vascularized pedicled flaps are generally preferred. Vascularized pedicled flaps are divided into sinonasal and scalp flaps [1,106].

The most commonly used vascularized sinonasal vascularized flaps are all based on branches of the sphenopalatine artery: *nasoseptal flap* [31] (Hadad-Bassagasteguy flap), *inferior turbinate flap*, and *middle turbinate flap*. Recently, some authors [104-105] have advocated the *naso-septal flap* as a safe and effective reconstruction for anterior skull base defects in the pediatric population, showing a success rate similar to open reconstructions. It is a robust mucoperiosteal-mucoperichondrial flap, potentially eligible for most skull base defects. The Hadad-Bassagasteguy flap is pedicled on the posterior septal artery, a branch of the sphenopalatine artery that runs along the inferior surface of the sphenoid ostium bilaterally. Therefore, if skull base reconstruction is planned, this artery must be preserved during sphenoidotomy. After the age of 13 years, the width and length of this flap have the same dimension of adults, whereas between 24 months and 10 years the length may be insufficient for repair of larger defects, thus requiring accurate pre-operative surgical planning. Under 24 months of age the nasoseptal flap is not recommended because of its limited overall dimensions [105]. Traditional scalp pedicled flaps are the *pericranial flap*, based on the supraorbital and supratrochlear arteries, the *temporoparietal fascial flap*, based on the superficial temporal artery, and the *temporalis muscle flap*, based on deep temporal arteries. For reconstruction of smaller anterior skull base defects, free grafts of iliotibial tract fascia and fat is a safe option, with high rate of success [1,106-107].

Juvenile Nasopharyngeal Angiofibroma

Juvenile nasopharyngeal angiofibroma (JNA) is a rare, benign, highly vascularized expansive lesion that typically affects male adolescents [108]. JNA has a controversial etio-pathogenesis, sharing features of both vascular malformations (origin from incomplete regression of the first branchial artery along its course) and tumors (chromosomal alterations, relentless growth) [109-112]. These lesions typically increase their growth rate following hormonal changes during puberty and can potentially regress when sexual hormonal levels decrease [113]. JNAs originate at the level of the sphenopalatine foramen, from where it extends typically to adjacent structures, widening skull base foramina and displacing fat, muscles, nerves, and vessels. This disorder has a peculiar propensity to expand infiltrating the

cancellous bone of the sphenoid, especially at the level of the vidian canal, pterygoid process, and middle cranial fossa floor [114].

Patients complain of recurrent spontaneous epistaxis with persistent monolateral nasal obstruction usually occurring in a young male adolescent. Less frequently, advanced JNAs can present with visual and ocular motility impairment, headache, conductive hearing loss, or facial pain/swelling and remodeling [114-115]. Nasal endoscopy shows a lobulated, rubbery, red-pink to gray mass covered by vascular structures, occupying the nasopharynx and nasal cavity. When JNA is suspected on nasal endoscopy, biopsy is strongly discouraged because of the high risk of high-flow bleeding [108,114]. MRI (Figure 11) is necessary to confirm diagnosis and for surgical planning. MRI is considered the gold standard diagnostic procedure, thanks to its optimal evaluation of sphenoid cancellous bone infiltration, involvement of cavernous sinus, orbital apex, and potential close relationship with the dura [108,114,116]. JNA is traditionally classified according to Andrews classification, as reported in Table 1 [117].

Transarterial embolization of the lesion, followed by its endoscopic transnasal resection is considered the mainstay of treatment [108,114].

Figure 11. At axial MRI, juvenile nasopharyngeal angiofibroma involves infratemporal fossa (arrow).

Table 1. Classification of juvenile nasopharyngeal angiofibroma according to Andrews [117]

Type I	Tumor limited to the nasopharynx and nasal cavity. No bone destruction or limited to the sphenopalatine foramen.
Type II	Tumor invading the pterygopalatine fossa or the maxillary, ethmoid or sphenoid sinus with bone destruction
Type III	Tumor invading the infratemporal fossa or orbital region: • IIIa: without intracranial extension • IIIb: with intracranial (parasellar) extradural involvement
Type IV	Intracranial intradural tumor: • IVa: without infiltration of the cavernous sinus, pituitary fossa or optic chiasm • IVb: with infiltration of the cavernous sinus, pituitary fossa or optic chiasm.

When present, postsurgical JNA residuals generally show an indolent course and can be effectively managed with a “wait-and-see” strategy, especially if located in critical areas. Revision surgery is usually reserved for symptomatic growing residuals [118].

Infantile Intranasal Hemangioma

Infantile hemangiomas are benign, painless, easily-bleeding, solitary lesions most commonly present in the skin and in the mucosa of the upper aerodigestive tract [119]. They are typically not observable at birth, but rapidly grow in the first months of life. Head and neck hemangiomas localize in the sinonasal tract in 7% - 29% of cases, typically involving the anterior portion of the nasal septum or head of the turbinates [48]. Sinonasal hemangiomas present with recurrent epistaxis and nasal obstruction. Local pain, headache, and hyposmia are rarely observed. Nasal endoscopy shows a reddish-purple, hypervascularized, easy-to-bleed, polypoid mass. MRI is generally required, especially when the actual extension of larger hemangiomas is not assessable with endoscopy [44,48]. Medical treatment of hemangiomas include propranolol, which reduces their size significantly [120-121]. Surgical intervention is generally reserved for symptomatic lesions with critical relationships with the orbit or skull base and/or non-response to medical therapy [93]. Wide endoscopic excision is generally sufficient. Pre-operative angio-embolization has been reported for large hemangiomas as an efficient strategy to reduce intra-operative bleeding [122].

Ameloblastoma

Ameloblastoma is a benign epithelial tumor that is derived from the dental lamina remnants or from the developing enamel organ. It is the most common odontogenic tumor, generally arising in the mandible or less frequently in the maxilla [123]. Primary sinonasal ameloblastoma is a rare condition [124]. No gender predilection has been reported. The peak of incidence is between the third and fifth decade, although ameloblastoma can occur in the pediatric population. Primary sinonasal and maxillary ameloblastoma with secondary extension in the sinonasal tract can be both asymptomatic or present as unilateral nasal obstruction, chronic/recurrent rhinosinusitis, bleeding, facial swelling, headache, and dizziness [124]. Radiographically, sinonasal ameloblastoma present as more commonly opacification of the nasal fossae and/or paranasal sinuses [125]. Imaging (CT and/or MRI) (Figure 12) is mandatory to identify the origin and extension of the lesion, and to plan its surgical removal. Children are more commonly affected by the unicystic subtype, with a lower rate of recurrence and better response to conservative treatment [123]. Trans-nasal endoscopic-assisted resection may be considered in primary sinonasal ameloblastoma and in combination with more traditional, open approaches for lesions arising in the maxilla and extending within the sinonasal tract [125,126].

Teratoma

Teratomas are rare neoplasms, with a reported incidence of 1 in 20,000-40,000 live births; however, they represent the most common type of germ cell tumor in the pediatric age [127]. They are formed by a heterogeneous mixture of tissues from each of the 3 embryonic germ layers (ectodermal, mesodermal, endodermal), such as hair follicles, teeth, bony, and muscular structures. They are rarely malignant. Up to 5% of pediatric teratomas occur in the head and neck region (nasopharynx, oropharynx, nasal cavities, orbit, cervical region, etc.). Larger teratomas are generally detected on prenatal ultrasound, allowing for prompt management at birth to secure the airway. Smaller lesions may present later as respiratory difficulties, dysmorphic features, or dysphagia, depending on their location [128]. Sinonasal and nasopharyngeal teratomas can be successfully treated endoscopically, avoiding palate splitting or resection with transoral approaches. Abnormal levels of serum alpha-fetoprotein during follow-up raise suspicion for recurrence.

Figure 12. Giant lesion (asterisk) occupies totally the right nasal fossa with displacement of the nasal septum (arrows).

Figure 13. Large lesion (white asterisk) involves rinopharynx and it expands anteriorly and laterally.

Sinonasal Malignancies

Pediatric sinonasal malignancies represent an extremely rare form of cancer, with a reported incidence of 0.036 per 100,000 individuals [129]. Although more commonly associated with male gender, a clear gender predominance has not been demonstrated in the pediatric population [129], [130]. These diseases commonly present with non-specific symptoms, such as monolateral nasal obstruction, epistaxis, facial pain/swelling, headache, ipsilateral visual acuity or ocular motility impairment, thus frequently delaying diagnosis to an advanced stage [129]. The most commonly affected sites are the nasal cavity, followed by the maxillary sinus, ethmoidal complex, and sphenoid sinus [131]. Diagnosis is based on biopsy of the lesion performed by a transnasal endoscopic approach and imaging (Figure 13), which allows to identify the origin and extension of the mass, involvement of nearby structures, and to hypothesize a histological diagnosis. Rhabdomyosarcoma is the most frequently observed histology, followed by NK-T cell lymphoma, olfactory neuroblastoma, and sarcoma. Mesenchymal tumors are more common in the first years of life, while the incidence of olfactory neuroblastoma increases during adolescence. When indicated, naso-ethmoidal malignancies can be treated through an endoscopic assisted wide removal with or without trans-nasal craniectomy and anterior skull base reconstruction. Prognosis is generally extremely poor and mostly depends on high grading and advanced staging at presentation. Both distant and local recurrences and failures are frequent [129-132]. Non-lymphoma sinonasal malignancies show a 5-year overall survival of 37.2% - 60.2% and a 20-year overall survival of 20.6% [129-130].

CONCLUSION

The use of transnasal endoscopic approach for the treatment of several sinonasal disorders in the pediatric age has radically modified long-term results. Endonasal optic fibers permit to identify and assess sinonasal sites that are not easily evaluated by traditional surgical procedures and to better evaluate relationships with adjacent anatomical structures. These advantages make PESS more precise and resolute. PESS is usually performed with good results for sinonasal inflammatory diseases, anatomical malformations, benign expansible lesions, benign tumors, and CFS-leak. The role of this surgical technique for malignant neoplasms is above all diagnostic. The therapeutic utility of PESS for these latter pathologies is limited to highly selected cases and to treatment of tumor residues.

Chapter 113

FEMTOSECOND LASER-ASSISTED REFRACTIVE SURGERY

Hui Sun*

Aerospace Information Research Institute, Chinese Academy of Sciences,
Beijing, China
University of Chinese Academy of Sciences, Beijing, China

ABSTRACT

A femtosecond is the SI unit of time equal to 10^{-15} of a second. The term “femtosecond laser” refers to a laser in which the pulse duration is in femtosecond range. Femtosecond laser has the advantage of combined high ablation precision and minimized collateral tissue effects, when creating photodisruption at corneal tissue. The accuracy and predictability of femtosecond lasers not only provides new treatment options, but also increases clinical outcomes in refractive procedures and corneal transplantations. The most important advantage of femtosecond laser technology is the ability to create vertical and lamellar corneal incisions with a limitless variety of shapes and angulations at a precise depth. The femtosecond laser technology has allowed a new era in the field of corneal transplantation surgery and it is now being used in a wide variety of corneal surgeries including customized trephination penetrating keratoplasty, anterior and posterior lamellar keratoplasty, tunnel creation for intrastromal ring segments, and astigmatic keratotomy. One of the most popular applications for femtosecond laser eye surgery has been laser in situ keratomileusis (LASIK) surgery, where the creating a corneal flap is a key step. Flap creation was originally performed by a mechanical microkeratome. Over the past two decades, femtosecond lasers have replaced the mechanical microkeratome as the dominant tool for LASIK flap creation in the United States, primarily due to its ability to create a thinner, flatter, and more even corneal flap. After a thin flap is created on the anterior surface of the cornea and lifted, the underlying corneal stroma is ablated by an excimer laser using direct photoablation. Today the entire procedure of LASIK can be accomplished independently with a femtosecond laser. At present, two approaches are used: one method is small incision lenticule extraction, which initial creates a corneal lenticule using the femtosecond laser, makes a cut around,

and performs the lenticule extraction. The other approach is femtosecond lenticule extraction, which utilizes a femtosecond laser to create the corneal flap, separates and extracts the lenticule from the corneal bed using a forceps, and manually restores the corneal flap. Because the application of femtosecond lasers in LASIK surgery is so successful and near-infrared wavelengths are almost not absorbed by optically clear tissue in the human eye, it is of no surprise that the application of these lasers to cut deeper eye tissues will be explored. The newest application of femtosecond lasers in ophthalmology is cataract surgery. Currently, there are a few lasers at or near the point of commercial release, including LenSx (Alcon Laboratories Inc., Fort Worth, Texas), Catalys (Abbott Medical Optics, Santa Ana, California), LensAR (LensARInc, Orlando, Florida), Victus (Technolas Perfect Vision and Bausch & Lomb, Rochester, New York), and Femto LDV (Ziemer Ophthalmic Systems AG, Port, Switzerland). All laser systems share a common platform, which includes an anterior-segment imaging system, patient interface, and femtosecond laser to image, to calculate and deliver the laser pulses. Some part of this chapter explains the principle of OCT-guided femtosecond laser cataract surgery. The combination of femtosecond laser surgery and OCT imaging simultaneously guides the development of next-generation femtosecond surgical lasers in cataract surgery and explores femtosecond-laser surgical strategies.

1. CONCEPTS RELATED TO FEMTOSECOND LASER-ASSISTED REFRACTIVE SURGERY

1.1. Femtosecond Laser

The name LASER is an acronym for “Light Amplification by the Stimulated Emission of Radiation.” A laser is a device that generates or amplifies coherent radiation at frequencies in the infrared, visible, or ultraviolet regions of the electromagnetic spectrum, which emits light through a process of optical amplification based on the stimulated emission of electromagnetic radiation [1]. A laser differs from other sources of light in that it emits light coherently. Spatial coherence allows a laser to be focused to a tight spot, enabling application such as laser cutting. Temporal coherence can be used to produce pulses of light as short as a femtosecond. A femtosecond is the SI unit of time equal to 10^{-15} of a second. The term “femtosecond laser” refers to a laser in which the pulse duration is in femtosecond range. Different types of lasers can produce femtosecond pulse like as dye lasers, solid state lasers, and fiber lasers. Solid state lasers are typically optically pumped, using either a flash lamp or laser diodes. Diode pumped solid state lasers tend to be much more efficient, and have become much more common as the cost of high-power semiconductor lasers has decreased. Single femtosecond laser pulse is employed to ablate eye tissue in femtosecond laser-assisted refractive surgery. The single laser pulse energy from oscillator cannot satisfy the threshold requirement even though the laser beam focused very well. A technique called chirped pulse amplification (CPA) is used for amplifying a femtosecond laser pulse to satisfy this intensity requirement was invented by G Mourou in the 1980s [2]. In order to keep the intensity of a femtosecond laser pulse below the threshold of the nonlinear effects inside the amplifier, this femtosecond laser pulse is stretched out in time prior to introducing it to the amplifier using a pair of gratings that are arranged so that the low-frequency component of the laser pulse travels a shorter path than the high-frequency component does. After going through the grating pair, the laser pulse becomes positively chirped, namely, the high-frequency

component lags behind the low-frequency component, and has longer pulse duration than the original one by a factor of 10^3 to 10^5 . Then the stretched pulse, whose intensity is sufficiently low, is safely introduced to the amplifier and amplified by a factor 10^3 or more. Finally, the amplified laser pulse is recompressed back to the femtosecond range through the reversal process of stretching, achieving orders of magnitude higher peak power than laser systems could generate before the invention of chirped pulse amplification technique.

1.2. Laser Tissue Interactions

We obtain more than 80% of our information from the external world by means of visual function. Good vision depends on the cornea and lens as refractive components. The cornea serves as the gateway into the eye for external images. The cornea accounts for more than two-thirds of the total refractive power of the eye. Maintenance of corneal shape and transparency is critical for refraction. Femtosecond laser has the advantage of combined high ablation precision and minimized collateral tissue effects, when creating laser induced ablation at corneal tissue. Numerous studies investigated the interaction of pulsed laser radiation with bulk material. A common finding is that the short pulse damage is deterministic in nature and the threshold is lower with shorter laser pulses. There are five types of laser tissue interaction: photochemical interactions, thermal interactions, photoablation, plasma-induced ablation, and photodisruption [3]. There are two types of laser tissue interactions which related to femtosecond laser-assisted refractive surgery: plasma-induced ablation, and photodisruption. A phenomenon called laser induced optical breakdown (LIOB) will occur when the power densities exceed 10^{11} W/cm² in solids and fluids or 10^{14} W/cm² in air. A bright plasma spark is clearly visible with this effect [3]. Without thermal or mechanical damage, the tissue is well defined and can be removed very cleanly. This kind of ablation is primarily caused by plasma ionization itself. Puliafito and Steinert describe the initiation of plasma generation as a two-fold process [4]. Either Q-switched pulses in the nanosecond range or mode locked laser pulses in the picosecond or femtosecond range can induce the microplasma. The first step is that a free electron absorbs a photon and accelerates. The second step is that the accelerated electron collides with another atom and ionizes it. The result is two free electrons, both having less individual kinetic energy than the initial electron. The third step is that these free electrons absorb photons, accelerate, strike other atoms, and release two more electrons. These steps will continue, and more and more free electrons will be induced. In order to achieve optical breakdown, the irradiance must be intense enough to cause rapid ionization so that the losses do not quench the electron avalanche. Due to the increased absorption coefficient of the induced plasma, an important feature of optical breakdown is that it renders an energy deposition in nominally weakly absorbing media. Therefore, transparent tissue like cornea or lens can become a target of medical laser application. Plasma formation and shock wave generation are physical effects associated with optical breakdown. Cavitation and jet formation may additionally take place if breakdown occurs inside soft tissues or fluids. Different from the plasma induced ablation, secondary effects of the plasma at higher pulse energies like shock waves become more significant. In the breakdown region the effect is plasma induced ablation while in the adjacent region the effects are shock wave and cavitation. Since adjacent tissue can be damaged by disruptive forces, the presence of these effects is often an undesired but associated symptom. The

difference between the plasma induced ablation and photodisruption is the different power energy during the process. Photodisruption is a multi-cause mechanical effect starting with optical breakdown. Shock wave generation and cavitation are the primary mechanisms, completed by jet formation if cavitation's collapse in fluids and near a solid boundary.

2. FEMTOSECOND LASER ASSISTED LASIK SURGERY

2.1. LASIK Surgery Procedure

An extension of wave front measurement technology to ophthalmology has quantitatively characterized the quality of the human eye. An exact measurement of aberrations induced by the eye opens the door for refractive surgery in the pursuit of perfect vision by a sophisticated surgical approach. The use of the excimer laser to directly alter the cornea curvature was made in photorefractive keratectomy (PRK) surgery. In 1995 the U.S. Food and Drug Administration (FDA) issued approval of the Summit (Waltham, MA) laser for PRK. In 1996 FDA approved the VISX (Santa Clara, CA) laser for PRK. At PRK surgery, the ablation starts from the front surface of the cornea. The excimer lasers direct split of molecular bonds with minimal adjacent heating. Because of the neural cells in epithelium, patients will feel pain during and after PRK surgery. New solution is to introduce a method which ablate the stroma after a flap is lifted. At this point, the excimer laser story joins the keratomileusis story to become Laser In-situ Keratomileusis (LASIK) [5]. This procedure consists of two steps. In the first step, a thin flap is created on the anterior surface of the cornea and lifted. This step involves cutting a thin flap in the cornea with a microkeratome in order to expose the stromal bed for excimer laser ablation. When flap is achieved, a hinge is left at one end of this flap. The flap is folded back, revealing the corneal stroma. In the second step, the underlying corneal stroma is ablated and then the corneal flap is replaced. The curvature of the cornea is altered by removing corneal tissue using direct photo ablation with ultraviolet light from the excimer laser. The excimer laser vaporizes the tissue in a finely controlled manner without damaging the adjacent stroma. No burning with heat or actual cutting is required to ablate the tissue. The layers of tissue removed are tens of micrometers thick. Performing the laser ablation in the deeper corneal stroma provides for more rapid visual recovery and less pain. The creating a corneal flap is a key step in LASIK. Flap creation was originally performed by a mechanical microkeratome. Over the past two decades, femtosecond lasers have replaced the mechanical microkeratome as the dominant tool for LASIK flap creation in the United States, primarily due to its ability to create a thinner, flatter, and more even corneal flap. Today the entire procedure of LASIK can be accomplished independently with a femtosecond laser. At present, two approaches are used: one method is small incision lenticule extraction, which initially creates a corneal lenticule using the femtosecond laser, makes a cut around, and performs the lenticule extraction. The other approach is femtosecond lenticule extraction, which utilizes a femtosecond laser to create the corneal flap, separates and extracts the lenticule from the corneal bed using a forceps, and manually restores the corneal flap.

2.2. Femtosecond Laser Assisted Flap Creation

Flap creation, a crucial step in LASIK procedure, was originally performed using a mechanical microkeratome. However, factors such as blade quality, gap width of the microkeratome head, and translation speed can affect the quality of the flap [6, 7]. Over the past two decades, femtosecond lasers have displaced the mechanical microkeratome as the dominant tool for LASIK flap creation in the United States, primarily due to enhanced precision and minimized collateral tissue effects [8-15]. Diode pumped all-solid-state femtosecond lasers are now commonly used to perform flap creation in LASIK. Yb-doped fiber lasers or solid-state lasers, which emit around 1 μm wavelength, are currently the most reliable systems and also the cheapest way to produce femtosecond lasers. Their pulse duration is typically around 200 to 800 femtoseconds. In 2000 the flap created by a femtosecond laser along with a refractive error corrected by the excimer laser was conducted on a patient for the first time. This procedure is called IntraLASIK, also known as Femto-LASIK or All-laser LASIK. The term IntraLASIK is derived from IntraLase, the name of the first manufacturer to achieve Food and Drug Administration approval of a femtosecond laser for use in the United States for the surgical procedure LASIK. For femtosecond laser flap creation, the patient's eye is fixed with disposable patient interface and the femtosecond laser focus first is scanned along a certain pattern inside the corneal stroma at a predetermined depth. The intrastromal cut is followed by several semicircular shaped cuts at decreasing depth in the cornea to connect this intrastromal cut to the corneal surface, with a hinge present to maintain connection to the cornea surface. After removal of patient interface then the flap is lifted to give the excimer laser access to deeper corneal stroma. A LASIK flap created with a femtosecond laser is regarded by many ophthalmologists as an improvement over traditional one created with a mechanical microkeratome because of a greater accuracy in flap size, shape, and thickness. Although the final long-term clinical outcome of LASIK with a mechanical microkeratome and with a femtosecond laser may be similar, the increased accuracy of the flap with the femtosecond laser provides an added margin of safety [16]. The femtosecond lasers have displaced the mechanical microkeratome as the dominant tool for LASIK flap creation in the United States today. Multiple commercial femtosecond lasers have now been cleared for use by the U.S. Food and Drug Administration for ophthalmic surgery, including for the creation of corneal flaps in LASIK surgery. Femtosecond laser systems have successfully entered the refractive surgery market since IntraLase (Irvine, California, USA), which was founded at Irvine, introduced its first commercial system in 2001 as a replacement for the mechanical microkeratome. Shortly after the market launch of the IntraLase laser, a company which is called 20/10 Perfect Vision (Heidelberg, Germany) introduced its FEMTEC system. Then, four years later, the Ziemer Ophthalmic Systems Group (Port, Switzerland) launched its DaVinci system (FEMTO LDV) in the late 2005, and exactly one year later, Zeiss introduced VisuMax (Carl Zeiss Meditec, Jena, Germany) in fall 2006. From 2008 to 2011, one more company enters this market. It is Alcon and the laser name is wavelight. At 2012, LenSx laser got the FDA approval for flap creation in LASIK surgery. It belongs to Alcon company (Fort Worth, Texas). Because Alcon was acquired by Novartis (Basel, Switzerland), now wavelight and LenSx are products of Novartis. The commercial systems on the market can be classified into two groups: one group is characterized by high pulse energy and low pulse frequency, Amplified laser systems are used to deliver pulse energy in the order of μJ to the cornea. The typical laser repetition rate is on

the order of kHz. Every CPA system belongs to this group. The other group is characterized by low pulse energy and high pulse frequency, which delivers energy on the order of nJ to the cornea. The typical laser repetition rate is on the order of MHz. DaVinci system belongs to this group. The nature of the ablating processes of the two groups is different. In the high pulse energy laser group, the cutting process is driven by mechanical forces, which are applied by the expanding bubbles and which disrupt the tissue. This is an efficient process because the radius of disrupted tissue is larger than the laser spot itself. In the low pulse energy laser group, the cutting process is confined by the focal spot size of the laser pulse so that more laser pulses are needed to cut the same spot size. The surface quality of the LASIK stromal bed seems to be of the same quality for these two groups.

3. FEMTOSECOND LASER ASSISTED CORNEAL TRANSPLANTATION SURGERY

The invention of the femtosecond laser technology has allowed great advances in the field of corneal surgery. The initial application of this technology is the flap creation in LASIK surgery. Further advances in this technology enabled the full thickness corneal cuts in a variety of patterns to be made. As a result, the femtosecond laser is now being used in corneal transplantation surgery [17]. The accuracy and predictability of femtosecond lasers not only provides new treatment options, but also increases clinical outcomes in refractive procedures and corneal transplantations. The most important advantage of femtosecond laser technology is the ability to create vertical and lamellar corneal incisions with a limitless variety of shapes and angulations at a precise depth. The femtosecond laser technology has allowed a new era in the field of corneal transplantation surgery and it is now being used in a wide variety of corneal surgeries including customized trephination penetrating keratoplasty, anterior and posterior lamellar keratoplasty, tunnel creation for intrastromal ring segments, and astigmatic keratotomy. The first machine to accomplish the full thickness corneal cuts for penetrating keratoplasty (PKP) was the Intralase. The second femtosecond laser platform to finish this work was FEMTEC. Results using femtosecond laser assisted PKP have generally shown a better fit between donor and host, larger surface area between the donor and host resulting in faster and improved wound healing, and less suture induced astigmatism. Femtosecond laser also used to treat the deep anterior lamellar keratoplasty (DALK). At this surgery, a technique that can maintain the patient's own healthy endothelial layer and replace the entire anterior stromal layer with the addition of superior wound edge healing and minimal induced astigmatism is ideal. The combination of the femtosecond laser-assisted custom shaped cut with the DALK big bubble technique achieves such a goal [17].

4. FEMTOSECOND LASER ASSISTED CATARACT SURGERY

4.1. Physical Concepts of Femtosecond-Laser-Assisted Cataract Surgery

The most prevalent ocular disease and the major cause of blindness in the world is cataract. Either clumps of protein or yellow brown pigment may be deposited in the lens reducing the transmission of light to the retina. Such opacity of the lens, whether it is a small

local opacity or a diffuse general loss of transparency is a cataract. The extent of people's visual disability decides the treatment decision for the patient with cataract. If the cataract is not seriously, the surgery maybe not need. But in most circumstances, there is no alternative to cataract surgery for correcting visual impairment. Under most circumstances, the standard of care in cataract surgery is removal of the cataract by two main types of surgical procedures throughout the world. The first procedure is phacoemulsification (PE or Phaco) and the second procedure is extracapsular cataract extraction (ECCE). PE is the most common technique used in United States today for cataract surgery. It involves the use of a machine with an ultrasonic to remove cataract. After the opening incision and anterior capsulotomy, an ultrasonic probe emulsifies the hard nucleus, enabling the ophthalmologist to remove the lens material using a suction device. The normal depth of the anterior chamber is maintained during this procedure. The wound is then enlarged to allow insertion of a posterior chamber intraocular lens (IOL) into the capsular bag. An IOL is usually implanted into the eye by two ways, either through a small incision using a foldable one, or through an enlarged incision using polymethylmethacrylate (PMMA) lens.

The state of the art of optical coherence tomography (OCT) is an interferometric imaging instrument. The basic principle of hardware of OCT is Michelson Interferometer. Today OCT is a clinical imaging technique that uses light to capture micrometer resolution and three-dimensional images from optical scattering within biological tissue. OCT is particularly suited to ophthalmic applications since it has micrometer resolution and millimeter penetration depth [18]. Like in Michelson Interferometer, light in an OCT system is split into two arms—a sample arm and a reference arm. When the light from both arms have traveled an optical distance which a difference of less than a coherence length of light, the combination of reflected light from the sample arm and reference light from the reference arm gives rises to an interference pattern. A reflectivity profile of the sample can be obtained through scanning the mirror in the reference arm. Interference will not happen when light is outside the short coherence length. Greater interference will create at areas of the sample that reflect back a lot of light. From the analysis of the such data the imaging of tissue will be achieved. An OCT system for ophthalmic use must have good image resolution, deep tissue penetration, and high scan speed. Anterior segment imaging and retinal imaging of the human eye are most common clinical application of OCT.

4.2. OCT Guided Femtosecond Laser Cataract Surgery Procedure

Because the application of femtosecond lasers in LASIK surgery is so successful and near-infrared wavelengths are almost not absorbed by optically clear tissue in the human eye, it is of no surprise that the application of these lasers to cut deeper eye tissues will be explored. Anterior segment femtosecond laser applications were investigated in many methods. To achieve this goal, an imaging technique for anterior segment need to be developed to assist the femtosecond laser ablation. The advent of all solid-state femtosecond lasers, coupled with computer-controlled beam delivery system, enables the new applications of high precision femtosecond laser ablation for ophthalmology. Combining with a precision imaging technique for anterior segment, such as an OCT system, can make it possible to accurate target of tissue in crystalline lens by femtosecond laser. It opened the door for femtosecond laser cataract surgery. Femtosecond laser systems have successfully entered the

cataract surgery market since LenSx (Alcon Laboratories Inc., Ft Worth, TX, USA), which was founded at Aliso Viejo in 2007, introduced its first commercial system in 2008 as a promising new technological advance which plays an ever increasing role in cataract surgery where it automates the three main surgical steps: corneal incision, capsulotomy and lens fragmentation. It is an innovative growing new technology for cataract surgery because the enhanced precision and minimized collateral tissue effects from femtosecond laser ablation. This attribute of femtosecond lasers is especially important for femtosecond laser cataract surgery, wherein preservation of ocular structures like capsular bag is critical for good visual outcomes [19]. The first clinical report of human eye treated by femtosecond laser cataract surgery was in Hungary in 2008 [20]. There has been increasing interest in the use of femtosecond laser in cataract surgery after the first report. The U.S. Food and Drug Administration approved the usage of femtosecond laser for cataract surgery in 2010. The application of femtosecond laser in cataract surgery increased dramatically after LenSx system was cleared for use by FDA. Just in a few years, femtosecond lasers have become relevant in cataract surgery in clinic as an opportunity to improve the quality of the surgical procedure. Currently, there are a few lasers at or near the point of commercial release, including LenSx (Alcon Laboratories Inc., Fort Worth, Texas), Catalys (Abbott Medical Optics, Santa Ana, California), LensAR (LensARInc, Orlando, Florida), Victus (Technolas Perfect Vision and Bausch & Lomb, Rochester, New York), and Femto LDV (Ziemer Ophthalmic Systems AG, Port, Switzerland). All laser systems share a common platform, which includes an anterior-segment imaging system, patient interface, and femtosecond laser to image, to calculate and deliver the laser pulses. They are solid state femtosecond lasers integrated with imaging subsystem. The principles are same but they differ in versatility, docking, and speed of action and so on. Although the steps for each laser platform vary, they share four primary steps for the femtosecond laser cataract surgery procedure: planning, engagement, visualization and customization, and treatment [19]. A series of parameters, such as pupil dilation, lens thickness, and corneal thickness, will need to be measured before cataract surgery. Then surgical plan will be made. Normally the planning parameters include the size, shape, and desired center of laser ablation for capsulotomy. The planning parameters also include diameter, depth, and patterns of cut for lens fragmentation. The planning parameters will include location, depth, and architecture of incisions for corneal incisions. Adjustments still can be performed in real time guiding by cross sectional imaging during cataract surgery. The patient interface optically couples the eye to the optical delivery system to prevent eye movement is the first clinical step for femtosecond-laser-assisted cataract surgery (FLACS). The docking system, namely patient interface, is comprised of a curved applanation lens and suction ring normally. Both parts are integrated into a single piece and mounted on the laser delivery system. Patient interface serves as a sterile barrier between the patient's eye and the femtosecond laser. All commercially available femtosecond lasers have appeared to be effective in stabilizing the patient's eye, however, the methods and devices for docking are an area of differentiation for these femtosecond lasers. The image guidance subsystem gives the instruction about the dimensions and location of ocular structures. It is a critical part of femtosecond laser cataract surgery because it guides the surgeon in lens fragmentation zones and placement of incisions. This subsystem must be able to detect the iris boundaries so that the surgery can be made safely without cutting iris. For the reason to maintain a safety zone and not cut in posterior capsule, this subsystem must be able to detect the posterior surface of the lens. The corneal thickness should be measured in order to

customize corneal incisions for each patient. The non-contact, fast method of high-resolution image acquisition with Fourier domain optical coherence tomography (FD-OCT) enables detailed cross-sectional imaging of the anterior segment useful in various clinical settings. Some important parameters for cataract, such as iris boundaries, corneal thickness, lens position, and iridocorneal angle can be measured by FD-OCT in real time. The platforms that using FD-OCT for three-dimensional, high resolution viewing of ocular structures in cataract surgery include LenSx, Catalys, Victus, and Femto LDV, while LensAR utilizes Scheimpflug imaging technology. The treatment is the final step of femtosecond laser cataract surgery. The femtosecond laser creates incisions through tightly focused femtosecond laser pulses that cut eye tissue with micron scale precision. The incision is achieved by contiguously placed femtosecond laser focus scanned by a computer-controlled delivery system through the laser spot pattern from posterior to anterior which will reduce the amount of radiation reaching the retina. The femtosecond laser beam creates individual photodisruption sites in a contiguous pattern to form continuous incisions. The spacing between each spot is programmed by the surgeon who programs the size, shape and location of the scanning pattern before the treatment. The treatment includes four parts, namely clear corneal incisions, creation of the capsulotomy, fragmentation of the lens nucleus, and correction of astigmatism through corresponding arcuate incisions.

The first clinical report of human eye treated by femtosecond laser cataract surgery was in Hungary in 2008 [20]. It is a promising new technological advance which plays an ever-increasing role in cataract surgery. The accumulating clinical experience to date with FLACS indicates that it offers several potential advantages over manual surgery are: a better quality of incision with reduced induced astigmatism; increased reliability and reproducibility of the capsulotomy with increased stability of the implanted lens; a reduction in the use of ultrasound [21]. Clear corneal self-sealing incision architecture is of paramount importance. Previous study shows the corneal incision with internal wound gape will increase the risk of leakage and thus postoperative endophthalmitis. Manual corneal incisions are difficult to control in terms of length and architecture. One of the benefits from FLACS is that corneal wounds and arcuate incisions in the desired position and depth make the control of postoperative astigmatism much more effective [22]. If FLACS can produce a reproducibly round, centered and intact anterior capsule, this alone would improve the safety of cataract surgery in a way that could possibly justify the introduction of this new technology [23]. The anterior capsular tears in the hands of experienced surgeons have a high incidence. There was a high ease of removal of the capsular button which created by femtosecond lasers. It is well known the importance of a precisely sized capsulorhexis to optimize intraocular lens (IOL) position and performance. FLACS can create capsulotomy more precise, rounder, more regularly shaped and greater centration than with a manual technique. This allowed for better intraocular lens and capsule overlap. The improved overlap of the anterior capsule by the IOL has been shown to produce less IOL tilt and decentration compared with manual continuous curvilinear capsulorhexis (CCC) [24]. A lot of similar results were obtained from commercially available femtosecond lasers in cataract surgery [25]. Femtosecond lasers are powerful tool to segment the crystalline lens, allowing the difficult chop steps in regular cataract surgery that most frequently lead to complications much easier. Femtosecond laser cuts on the crystalline lens soften the harder cataracts with a result of decrease the amount of ultrasound energy from the phacemulsification probe, thereby diminishing the risk of capsule complications and corneal endothelial injury. To date, the clinical reports showed the

percentage reduction of FLACS phachemulsification varied by company and grade of cataract, but was 33% at least [26, 27]. Other benefits of FLACS include it has the ability to correct of astigmatism through corresponding arcuate incisions, reduction of infection possibility, decreased endothelial cell loss and maybe better visual and refractive outcomes.

CONCLUSION

Femtosecond laser has the advantage of combined high ablation precision and minimized collateral tissue effects, when creating photodisruption at corneal tissue. The accuracy and predictability of femtosecond lasers not only provides new treatment options, but also increases clinical outcomes in refractive procedures and corneal transplantations. One of the most popular applications for femtosecond laser eye surgery has been laser in situ keratomileusis surgery, where the creating a corneal flap is a key step. Flap creation was originally performed by a mechanical microkeratome. Over the past two decades, femtosecond lasers have replaced the mechanical microkeratome as the dominant tool for LASIK flap creation in the United States, primarily due to its ability to create a thinner, flatter, and more even corneal flap. Today the entire procedure of LASIK can be accomplished independently with a femtosecond laser. Femtosecond laser-assisted corneal surgery is improving traditional outcomes in transplantation. The femtosecond laser technology has allowed a new era in the field of corneal transplantation surgery and it is now being used in a wide variety of corneal surgeries including customized trephination penetrating keratoplasty, anterior and posterior lamellar keratoplasty, tunnel creation for intrastromal ring segments, and astigmatic keratotomy. The advent of all solid-state femtosecond lasers, coupled with computer-controlled beam delivery system, enables the new applications of high precision femtosecond laser ablation for ophthalmology. Combining with a precision imaging technique for anterior segment, such as an OCT system, can make it possible to accurate target of tissue in crystalline lens by femtosecond laser. Femtosecond laser systems have successfully entered the cataract surgery market as a promising new technological advance. The clinical experiences so far indicate that this new technology is promising for the field of cataract surgery. FLACS appears safe and efficacious, and may eventually be proven superior to conventional cataract surgery.

ABSTRACT

Surgical intervention plays a crucial role in the diagnosis, staging, and treatment of malignant pleural mesothelioma (MPM) and can apply with curative intent using extended pleurectomy/decortication or extrapleural pneumonectomy (EPP).

EPP is defined as the en-bloc resection of the pleura, lung, diaphragm, and pericardium, excision of previous biopsy and chest tube sites, and radical mediastinal lymphadenectomy and other lymph nodes such as found in the mammary chain, along the intercostal structure and in the costodiaphragmatic region, as well as reconstruction of the diaphragm and pericardium with prosthetic patches to prevent herniation. It was shown that EPP could be performed with acceptable morbidity and mortality. One of the most complex decisions is the surgical indication. Laparoscopy or contralateral pleuroscopy should be performed in case of suspicion of intra-abdominal or contralateral disease in staging imaging. Mediastinal staging is performed via endobronchial ultrasound or mediastinoscopy to exclude N3 disease. The analysis of prognostic factors to identify patient groups benefitting from multimodality therapy led to the development of different prognostic scores, such as the Multimodality Prognostic Score. Technical experience has led to decreased operative times and surgical adaptations that include the reconstruction of the diaphragm and pericardium with mesh in all patients regardless of side, buttressing of the bronchial stump with well-vascularized tissue, and advanced methods of

haemostasis including argon beam coagulation and topical haemostatic agents for chest wall bleeding.

Keywords: extrapleural pneumonectomy, malignant pleural mesothelioma, thoracic surgery

INTRODUCTION

The technique of tumour resection for malignant pleural mesothelioma (MPM) is one of the most debated topics in thoracic surgery, mainly as more significant analyses confirm that even the most aggressive surgical approaches rarely result in cure or long-term survival. Butchart first applied pleuro-pneumonectomy in 1976; on the other hands, en bloc diaphragm and pericardial resection were performed in most cases. To date, the evidence has still significant deficiencies due to the lack of prospective comparative analyses. Despite this, surgery continues to play a significant role in the management of MPM, with the achievement of macroscopic resection of tumour [1].

Table 1. IASLC definitions of surgical procedures for malignant pleural mesothelioma [12]

Extrapleural pneumonectomy	En bloc resection of the visceral and parietal pleura, pericardium, ipsilateral hemidiaphragm, and lung
Pleurectomy/Decortication	Resection of the parietal and visceral pleura, to remove all gross tumours, without removing diaphragm and pericardium
Extended Pleurectomy/Decortication	Pleurectomy/Decortication with the resection of ipsilateral diaphragm and pericardium
Partial pleurectomy	Partial removal of the parietal and/or visceral pleura for diagnostic or palliative intentions

TECHNICAL DEFINITION

The chaos of surgical terminology in MPM was standardised and refined by the International Association for Study of Lung Cancer (IASLC) in 2011. Extrapleural pneumonectomy (EPP) was defined as en bloc resection of the parietal and visceral pleura with the ipsilateral lung, pericardium, and diaphragm. Extended pleurectomy/decortication (P/D) was defined as parietal and visceral pleurectomy to remove all gross tumour with resection of the diaphragm and/or pericardium (Table 1) [1].

OBJECTIVES OF SURGICAL TREATMENT

Surgery can help to achieve an correct diagnosis of MPM (open or VATS pleural biopsies) or to palliate symptoms caused by malignant pleural effusions (VATS talc pleurodesis, pleurectomy, placement of indwelling pleural drainage). In very selected patients (early-stage disease and satisfactory performance status), radical surgical procedures have

been offered in the past, with or without different neoadjuvant or adjuvant treatments. Whenever aggressive surgery is planned, it aims to remove all gross disease, lengthening survival by reducing the intrathoracic tumour burden to microscopic levels. Due to biological characteristics of MPM, the intrathoracic anatomical structures may be rapidly invaded by the tumour, generally without the development of distant metastases. This loco-regional tumour invasiveness should be considered when a surgical approach is planned. MPM surgery is a maximal cytoreductive procedure and usually results in an R1 resection. An R0 resection with surgery alone is theoretically unobtainable, regardless of the type of aggressive procedure is chosen. Consequently, the first goal of surgery is to achieve a complete macroscopic resection; other treatment modalities have been combined with surgery, to control the residual microscopic disease. Patients should undergo this treatment in the setting of a multidisciplinary tumour board, where the single clinical cases are carefully discussed. Ideally, all candidates for surgery should be operated in Thoracic Surgery Units with recognised broad experience in MPM management, commonly connected with Medical and Radiation Oncology Divisions also involved in clinical trials for MPM. The secondary goal for surgery is to achieve a local tumour control (evacuate pleural effusions, palliate chest pain and ameliorate ventilation/perfusion mismatch) [2].

PROGNOSTIC FACTORS AND PATIENT SELECTION

This risk factors significantly impact on survival in patients undergoing surgery:

- T stage (most apparent in patients undergoing surgery with curative intent);
- Nodal status;
- Tumour histology (epithelial with better outcomes);
- Gender and age;
- Curative intent.

Such factors are critical in the determination as to whether an individual patient may benefit from surgical resection where removal of the macroscopic tumour is the goal. Surgical resection with the goal of removal of the macroscopic tumour can be considered in only a small percentage of patients with MPM. That distant and/or local recurrences are inevitable after aggressive surgical approaches, unfortunately, emphasise that these procedures are not curative. Therefore, the demonstration of a meaningful impact of surgery in the form of prolongation of overall survival without significant morbidity or detrimental impact on the quality of life is needed but is currently lacking. Multidisciplinary management and treatment planning at centres that are experienced in MPM management should be the norm for patients with this disease, given the relatively small number of cases that present every year. Institutional bias and practice will continue to have a significant influence on the surgical approaches used, and the selection that occurs in the accrual and reporting of small multimodality trials makes it difficult to incorporate neoadjuvant or adjuvant therapies with confidence. However, one current randomised trial should provide valuable data in the future [3].

SURGICAL TECHNIQUE

EPP was always performed via double lateral thoracotomy (first thoracotomy through IV-V intercostal space and second thoracotomy through VII-VIII intercostal space) with en bloc excision of the parietal pleura with the entire lung, ipsilateral hemidiaphragm and pericardium. The diaphragm was reconstructed with a synthetic dual mesh placed in the anatomic position of the resected diaphragm or with the bovine pericardium. The pericardium was reconstructed both on the right and on the left sides to prevent cardiac torsion using a synthetic mesh or bovine pericardium. Lymph node dissection should be performed in all patients. Surgery was always performed within four weeks after the last cycle of induction chemotherapy [4].

PERIOPERATIVE MANAGEMENT

Preparation for EPP by the anesthesiologist includes placement of routine monitors, lines, and an epidural catheter for perioperative regional pain control. An arterial line is needed owing to rapid hemodynamic changes and large-bore intravenous access, including a central line, is recommended. If there is any concern regarding pulmonary hypertension, a Swan-Ganz catheter is floated with caution to pull this back before pulmonary artery division. Central lines should be placed on the operative side to avoid pneumothorax on the side of the ventilated (and postoperatively, only) lung. Lung isolation may be obtained with a double-lumen endotracheal tube (preferred) or bronchial blocker, with the latter to be pulled back before the division of the bronchus. Finally, a nasogastric tube is inserted to aid in identifying the oesophagus intraoperatively and to decompress the stomach postoperatively. The disruption of vagal fibres to the bronchus often causes mild postoperative oesophageal dysmotility, and nasogastric decompression may prevent life-threatening aspiration after pneumonectomy in the early postoperative period [5].

PREOPERATIVE EVALUATION

Patients diagnosed with MPM who are considered for EPP are staged with Positron Emission Tomography/Computed Tomography (PET/CT) to evaluate for nodal or distant metastases. The level of PET avidity of the pleural tumour has been shown to correlate with survival, with higher avidity associated with lesser survival. Enlarged and/or PET-positive mediastinal lymph nodes are evaluated with endobronchial ultrasonography or cervical mediastinoscopy. Although some centres perform routine staging mediastinoscopy in all patients, others have abandoned this because of the variable nodal drainage of the pleura with an unpredictable pattern of nodal metastases and the lack of sensitivity of cervical mediastinoscopy for detecting extrapleural nodal spread in MPM. Chest Magnetic Resonance is often performed to evaluate for thin chest wall, transdiaphragmatic, or transmediastinal invasion of the tumour. The presence of a transdiaphragmatic extension of the tumour and/or ascites warrants further evaluation with staging laparoscopy because intraabdominal tumour would preclude surgical resection. The remaining preoperative evaluation is to determine the

patient's ability to tolerate EPP. Pulmonary function tests, including spirometry and diffusion lung capacity, should be performed. Quantitative ventilation/perfusion scan is routinely done to assess perfusion to the affected lung. The product of the proportion of perfusion to the contralateral lung (which will remain after pneumonectomy) and the forced expiratory volume in 1 second (FEV1) is the predicted postoperative FEV1. Although many clinicians recommend a value of at least 800 mL for pneumonectomy, the added morbidity of extrapleural, diaphragmatic, and pericardial resection have led most surgeons to consider a higher level, such as 1.2 L, for all but the smallest patients. Both a stress test to rule out inducible myocardial ischemia from coronary artery disease and an echocardiogram with Doppler estimation of pulmonary artery pressure based on tricuspid regurgitation should also be performed. A patient with pre-existing pulmonary hypertension may not survive the added right ventricular strain of pneumonectomy. Finally, duplex ultrasound of the lower extremity veins to rule out deep vein thrombosis, particularly in patients who have undergone neoadjuvant therapy, is performed. MPM patients have a high incidence of occult deep vein thrombosis and preoperative treatment with anticoagulation (and possibly inferior vena cava filter) may reduce the risk of fatal pulmonary embolus after pneumonectomy [6].

COMMENTS

Nevertheless, current literature favours P/D to EPP for several reasons. As P/D is a procedure with lower morbidity and mortality, it seems to be the most logical and preferred choice in the treatment of MPM. Others suggest that EPP should one day become of historical interest only due to repeated analyses of historical datasets that fail to show a benefit to EPP over P/D. So, P/D is indicated in most cases, except those with extensive tumour invasion into the pulmonary parenchyma. Resection of the diaphragm, pericardium, and lung parenchyma is performed if required. Conversion to EPP is decided based on intraoperative findings. This concept is supported by other paper in the literature who state that patients who are scheduled for P/D should be prepared to undergo EPP in case of extensive lung infiltration discovered during surgery as one surgical procedure does not fit for all patients with MPM. Lung preservation should be achieved whenever possible, but EPP may be a valuable solution in selected cases. The Clinical Practice Guidelines of the European Society of Medical Oncology (ESMO) on MPM do not advocate a specific procedure to perform a complete macroscopic resection [7]. The NCCN guidelines on MPM suggest P/D may be safer than EPP in early-stage disease with favourable histology but does not conclude on which procedure is oncologically superior because of the lack of adequately designed well-performed randomised controlled trials. In more advanced disease, P/D reduces the risk for perioperative mortality and may be acceptable in terms of achieving complete macroscopic resection [8]. However, the decision about whether to do P/D or EPP may not be made until surgical exploration [9]. Literature reports yield evidence that the success of EPP in skilled referral centres, when part of multimodality treatment, depends on a good selection of patients with appropriate variables and technically favourable conditions to reduce the usually high perioperative morbidity and mortality rates and improve the overall survival. Younger women with epithelial histology type of disease and undergoing induction chemotherapy could be considered the best group of patients to propose EPP, as a part of multimodality

treatment, with an estimated 2-year survival up to 68% [10]. For many years, EPP was the only surgical procedure which achieves a complete macroscopic resection, and it was applied in treatable patients independent of stage and histology. In some individuals with very early disease, a P/D was performed to preserve the lungs. Since the OS of patients after P/D is not different compared to EPP, most groups started a transition from EPP to P/D in most patients over the last years. However, as in other malignancies, one procedure does not fit for all, and there are situations, in which a patient may require an EPP in order to obtain a complete mesothelioma resection and still have a “functioning” lung left behind. This can be anticipated from the CT scan, but the final decision is sometimes made during surgery only. This is typically the case in tumours with relevant lung parenchyma infiltration and preferentially on the left side as an EPP is usually better tolerated. Therefore, patients foreseen for a P/D should be prepared to undergo EPP in case of extensive lung infiltration discovered during surgery. Not only during patients informed consent discussion, the patient should be informed about EPP, but also preoperative functional assessments must be performed accordingly [11].

CONCLUSION

The surgical technique in MPM aims to achieve a complete macroscopic resection. The best technique to achieve this was with EPP in the beginning. The technique of EPP, a morbid and risky procedure, has been refined over time and became a procedure with acceptable morbidity and mortality. In several large patient series of EPP and P/D, there was no difference in terms of long-term survival. The main prognostic factors were epithelioid histology, extrapleural lymph node metastasis and completion of multimodality treatment.

ABSTRACT

The regeneration of oral tissues depends on the body's natural capacity and the materials and techniques currently available. Bone loss in the cranio-maxillo-facial region because of trauma, anatomical or congenital causes, cancer, and bone disease requires surgical intervention. The proposed techniques include treatment with bone grafts, bone substitutes, distraction osteogenesis and guided tissue regeneration (GTR), as well as their combinations. Research in this area has been advancing. The most recent developments in tissue engineering and stem cell and gene therapy have been used in the maxillofacial surgery with good results. Tissue engineering can be divided into conductive, inductive, and cell transplantation modes. GTR is a conductive technique. This procedure, which uses biomaterials to facilitate the growth or regeneration of already existing tissue, entails using a resorbable or non-resorbable membrane that excludes undesirable types of tissue growth and permits only bone cells to populate the surgically treated site, thus guiding the whole regeneration process. Among the indications for the use of GTR technique in maxillofacial surgery are oronasal fissures requiring surgical treatment, oro-antral communication, maxillary sinus lift, increasing the height and thickness of insufficient alveolar ridge for the placement of endosseous implants and prosthetic rehabilitation, and maxillary and mandibular bone changes that require appropriate aesthetic and functional reconstruction. Depending on the size and location of the defect, various surgical techniques for bone regeneration have been described in the literature. The choice of appropriate treatment is a difficult and complex process. The technique of GTR is feasible with good prognosis, when used properly

following the basic requirements for the correct application of the membranes. Over the past several years, new concepts and materials have been developed with the aim of increasing the therapeutic arsenal of professionals employing tissue regeneration therapies. This chapter will describe the use of GTR techniques in maxillofacial surgery, as well as the materials used in this procedure and different experimental models studied.

Keywords: guided tissue regeneration, guided bone regeneration, maxillofacial surgery

UNIT 1 – TISSUE ENGINEERING IN THE MAXILLOFACIAL SURGERIES

Tissue loss resulting from trauma, anatomical reasons or congenital abnormalities, cancer, and bone disease, is a major health concern. Besides being impaired physiologically, many of these patients are affected psychologically, especially when the damage occurs in the craniofacial region [1]. Craniofacial deformities have an enormous impact on psychosocial interactions in the lives of these patients [2]. Functional and aesthetic requirements in the management of facial surgeries have steadily increased in the last decade [3]. It is necessary to restore not only the structure and function, but also the aesthetics, to restore the self-esteem of these patients.

The regeneration in the oral maxillofacial area depends on the systemic health status of the patients, in addition to the materials and techniques currently available.

Although tissues of the oral complex exhibit regenerative capacity in response to disease or trauma, damage to these tissues can at many times be irreversible [4]. Researchers in this area have focused their efforts on developing methods based on tissue engineering and gene therapy for oro-facial reconstruction [5]. The attempts to regenerate fully functional tissue will result in multiple solutions that are beneficial for the future of craniofacial medicine [6].

Using mechanical devices, with little consideration to the effects on local cells and tissues [1], has given way to today's regenerative medicine using the techniques of tissue engineering as well as bioactive materials in combination with cells and/or biological molecules capable of inducing cell proliferation, to regenerate a functional replacement tissue at a diseased or damaged site [1].

There has been a shift from the use of materials that simply replace tissue in a non-functional manner, to that of utilizing specific materials, which will regenerate fully functional and structurally acceptable tissue.

Disfigurement and extension of a defect seen in clefts and long-lasting defects after trauma or tumor surgery, affecting speech, mastication, deglutition, and respiration, demand a restoration that is as close to normal physiological functionality as possible [3]. Synthetic materials cannot replicate the physiological properties of the original tissue [4].

Thus, the simple replacement of fully functioning sets with metal prostheses in the 60s, when the materials were thought to be 'inert', has made room to materials that are physically, chemically, and biologically capable of effectively replacing the damaged or diseased tissue with repaired or regenerated tissue [1].

The discovery of stem cells and developments in cellular and molecular biology have led to new therapeutic strategies for the regeneration of tissues that were injured by disease [3].

Tissue engineering is a multidisciplinary field that involves the principles of engineering and life sciences, biology and clinical medicine, for the development of biological substitutes

that restore or improve tissue function [3, 7]. It is based on the fundamental principles of identifying appropriate cells, developing scaffolds and identifying the morphogenic signals required to stimulate cells to regenerate a tissue [3]. There are 3 major classes of tissue engineering techniques: conductive, inductive, and cell transplantation [4, 7].

Cell substitutes allow the replacement of only those cells that supply the needed function [7] and involve direct introduction of tissue that has been manipulated earlier *in vitro*. An example is cell transplantation, which involves taking existing tissue from the patient, isolating and multiplying the desired cells, and inserting them back into the patient at the defect site, to bring about tissue regeneration [4]. Limitations of this method include failure of the infused cells to maintain their function at the transplantation site [7].

The approach of using inductive substances depends on the purification and large-scale production of appropriate signaling molecules, such as bone morphogenetic proteins and platelet-derived growth factor [4], and the development of methods to deliver these molecules to the target sites [7], to stimulate surviving cells and promote regeneration [4].

The conductive technique, such as guided tissue regeneration (GTR), uses biomaterials to facilitate the growth of existing tissue or regeneration of new tissue [4]. In closed systems, a cell occlusive membrane that is permeable to nutrients and wastes but keeps out large entities such as antibodies or immune cells that destroy the transplant, is used. In open systems, cells attached to matrices are implanted and get incorporated into the body [7].

The choice of the method for regenerating lost tissue depends on factors such as the size of the defect, supply of cells from adjacent areas, cell migration rate, and presence of vasculature in the surrounding areas [6].

When the clinical need is the regeneration of a small amount of tissue, conductive and inductive techniques are utilized to recruit cells from host tissue into a scaffold, whereas regeneration in large defects often requires the direct transplantation of cells. If cells are not present in the surrounding tissue in sufficient quantities to populate the defect, depending solely on cell migration would require an unacceptably long healing time [6].

As early as in 1993, Langer & Vacanti [7] discussed the future of tissue engineering research. Researchers need to continuously explore various aspects of cell biology, regarding the causes of cellular differentiation and growth, and the relationship of the extracellular matrix with cell function. The study of molecular genetics will lead to the design of cells and materials that are not rejected by the immune system.

The ultimate goal of tissue engineering is to engineer virtually every type of tissue, including nervous tissue, cornea, skin, liver, pancreas, tubular structures, cartilage, bone, muscle, and vascular tissue [7].

UNIT 2 – INTRODUCTION TO GTR IN MAXILLOFACIAL SURGERY

GTR, based on the principle of *in situ* tissue regeneration, also termed “endogenous regeneration,” stimulates the intrinsic potential of a tissue to heal or regenerate [8]. GTR, a conductive approach uses a natural or synthetic matrix that acts as a scaffold or barrier on which cells can attach, proliferate, migrate, and differentiate [6]. The ultimate aim of the regenerative therapy is the restoration of lost tissue form and function.

In 1980, Nyman et al. [9] developed the concept of GTR based on the principle that specific cells would contribute to the formation of specific tissues. Melcher [10] described in 1976, the concept of repopulation of defects by specific cell types to enhance healing. Exclusion from the defect site of tissues that grow faster than bone tissue, such as epithelium and connective tissue, facilitates the growth of desired tissues such as bone, into the defect site [11].

In GTR, a resorbable or nonresorbable barrier membrane is used to prevent the invasion of the defect site by undesirable cells [4]. Non-resorbable membranes require a re-entry procedure to remove them, and are prone to exposure and infection. In contrast, resorbable membranes do not require re-entry. However, these are frequently used in combination with grafts that provide support to the membrane [4].

Thus, GTR, a conductive technique, uses membranes alone or a combination of membranes and bone grafts, to guide the formation of new tissue. It can also employ inductive methods and bioactive scaffolds, which stimulate cell migration and proliferation [6, 12]. Various growth factors can also be used in this procedure.

The scaffold supports the proliferation of cells in the remaining tissue while it breaks down over time. The membrane allows the proliferation of desired cells in the defect site, and excludes undesirable cells. The growth factors, if used, their rate of release at the defect site as well as the quantity should be controlled. It is also necessary to control the rate of membrane degradation to ensure space maintenance long enough for new tissue formation.

Bone graft scaffolds represent the extracellular matrix (ECM), and the membrane isolates the necessary cells to proliferate and regenerate lost tissue.

Understanding of the development of tissues and organs during embryogenesis and the mechanism by which they remodel and maintain their functionalities are the prime sources of information for designing synthetic ECM used in tissue engineering and regeneration [13].

The synthetic ECMs provide structural support to tissues and play role in controlling cell adhesion, migration, growth, and differentiation via intracellular signaling pathways [13].

In the conductive technique, synthetic ECMs maintain space to allow host cell infiltration into the tissue defect site [13]. The synthetic ECMs are often used as depots of growth factors and control their release at the defect site. Similar to native ECM molecules, adhesive signals can be incorporated into the matrix to control cell migration from the surrounding tissue into the defect site [13].

Types of Membranes Used in GTR

Many factors contribute to a successful GTR outcome, including adequate barrier properties, biocompatibility, space maintenance, cell-occlusiveness, tissue integration, and clinical manageability [14].

Biomembranes are used as barriers to prevent the invasion of the defect site by undesirable cells and allow the slow migration of cells to restock the area [15]. Numerous barrier membranes have been developed, and can be grouped into resorbable or non-resorbable varieties.

Resorbable membranes are natural or synthetic polymers. Most popular ones are collagen and aliphatic polyester membranes [13, 14].

Among the non-resorbable membranes, expanded polytetrafluoroethylene (e-PTFE) and titanium mesh are the most widely used barriers [14].

Membrane e-PTFE is a practically inert substance that exhibits a low coefficient of friction, impermeability, and low adherence [15]. These membranes provide an effective barrier function in terms of biocompatibility and can maintain the space beneath the membrane for a sufficient period, beyond which they have a reduced risk of long-term complications [14]. All these advantages overcome the major disadvantage of the necessity for removal using a second surgical procedure [14].

Another nonresorbable material applicable for dental bone repair is titanium mesh, which was previously studied by Boyne et al. in 1969 [16], for the reconstruction of large discontinuous osseous defects [14, 16].

Titanium has been used extensively because of its high strength and rigidity, low density and weight, ability to withstand high temperatures, and resistance to corrosion [14]. According with Degidi et al. [17], titanium mesh is helpful for maintaining space in large mandibular and maxillary defects [17, 18].

However, to eliminate the need for a second surgery to remove the membrane, resorbable membranes, which should be fully absorbed, must be used without causing major damage during the healing process.

In principle, stiff resorbable membranes promote a similar degree of bone regeneration and bone formation as nonresorbable membranes [14].

Collagen is the main structural macromolecule of the human body and can be used for membrane fabrication via multiple methods. However, native collagen is degraded within a few days, and untreated collagen membranes lack stability to maintain space if a bony support is missing. To overcome these problems, various crosslinking techniques have been developed, leading to the development of stiffer collagen membranes and slowing enzymatic degradation [19].

Polyglycolide or polylactide (aliphatic polyesters) can be prepared in large quantities and allows for the creation of a wide spectrum of membranes with different physical, chemical, and mechanical properties [14, 20].

UNIT 3 – GTR IN OSSEOUS OR GUIDED BONE REGENERATION

The shape and contour of the head region depends on the mechanical integrity of bone tissue and functions to protect the soft tissues of the cranial cavity [6, 21]. Approximately 800,000 bone grafting procedures are completed each year in the United States of America [22], and restoring or enhancing the repair of bone is a crucial problem in orthopedics and dentistry [13].

Advanced atrophy or jaw defects, cleft palates, bony nasal pyramid defects following removal of a fistulous tract or cyst, extreme deficiency of the chin, scoliosis of the mandibular arch, mandibular asymmetry, and defects following removal of sinus and mandibular tumors all require the generation of novel bone tissue [23]. Car accidents, sporting activities, and gunshot wounds can also result in blowout fractures of the orbital floor, orbital rim fractures, craniocerebral trauma, malunited fractures, major fractures of the maxilla or mandible, osteoradionecrosis, and dento-alveolar trauma [6, 23].

Various attempts have been made to reconstruct craniofacial tissues, including application of bone or bone substitutes as autogenous grafts, allogeneic grafts, xenografts [4], demineralized bone matrices, synthetic bone pastes, semisynthetic scaffolds, and various alloplastic materials.

Although each method can achieve the objective of tissue restoration, these methods all have limitations, such as donor site morbidity, graft resorption, contour irregularities, insufficient autogenous resources, disease transmission, major histoincompatibility, graft-versus-host disease, immunosuppression, structural failure, stress shielding, and infection by foreign material [2].

Among the graft materials used for bone regeneration, autogenous bone is considered an ideal material because it shows increased capacity for bone formation, osteoconduction, and osteoinduction; it does not induce immunological rejection; and heals rapidly [24, 25]. Additionally, autogenous bone grafts are limited by the inability to harvest large amounts of tissue [24], significant bone resorption, harvesting difficulties, donor site pain, and poor contouring [6, 23]. Several types of allografts and xenografts are available; however, disease transmission and immunorejection remain substantial obstacles to their implementation [6]. Synthetic bone replacements are also utilized; however, these materials generally fail over time and may show problems with biocompatibility [6, 13].

Thus, engineering tissue with the ideal features may allow formation new bone tissue through osteoconduction, osteoinduction, and cell transplantation strategies [6, 13].

In extensive reconstruction, transfer techniques for vascularized osseous bone are often used and include osseo- and cutaneous-free flaps, which are primarily applied in oncologic surgery of the head and neck region [3]. Additionally, bone block transplantation is used in cases of advanced atrophy or jaw defects before application of surgical preprosthetics to enable patients to be fitted with implants [3]. This is a necessary surgical step in the extra-oral region because of need for large-volume grafts, such as grafts in the fibula, scapula, and iliac crest, causing donor-site morbidity [26, 27]. To achieve adequate bone regeneration, adequate scaffolds and appropriate cells of the annex are needed, showing adequate proliferation and differentiation [3].

Osteoconductive approaches using engineering tissue may allow infiltration of osteoprogenitors from the bone marrow into local defects while providing temporary mechanical support; this is called guided bone regeneration (GBR) [13].

Through a combination of transplanted biomaterials, stem cells, an appropriate mixture of regulatory factors that stimulate cellular growth and proliferation, and extracellular matrix components to allow the growth and specialization of the cells, important clinical applications in alveolar bone surgery and facial skull surgery may be achieved [3, 28].

Anatomical sealing has been employed in periodontics to allow regeneration of materials providing tooth support, i.e., the GTR. By covering the tooth roots of monkeys with membranes, Gottlow et al. [29] observed that the membrane and root were involved in bone regeneration and concluded that the principles of GTR can be used in GBR.

In addition to the membranes, scaffolds can also be used for GBR. For example, scaffolds of synthetic extracellular matrix can promote osteoconduction according to the distribution of pore diameters. Thus, the surface in contact with the bone tissue requires the largest pores, allowing cell conduction to occur more easily. In contrast, the surface in contact with fibroblasts requires smaller pores to inhibit cell proliferation. Therefore, the material blocks

undesired cells types, while allowing cell types that can form bone to migrate into the site [13].

Utilization of growth factors may enhance the utilization of grafts. Urist demonstrated the capabilities of demineralized bone matrixes to form bone using rat muscle, proposing that growth factors can induce bone formation independently of the bone tissue condition [18].

To date, researchers have identified many growth factors, including bone morphogenetic protein (BMP) and growth factor beta (TGF- β). BMP is an osteoinductive growth factor that reduces the need for autogenous bone grafts [18] and has an essential role in the regulation of bone formation, maintenance, and repair [4]. Among these roles, recombinant human BMP-2 has been approved for use in sinus augmentation [4] and for localized alveolar ridge augmentation for defects associated with extraction sockets [18].

Platelet-rich plasma (PRP) is a platelet concentrate that contains a number of growth factors, including TGF- β . PRP can be prepared chair side with minimal complications because PRP is an autologous material. Utilization of PRP has been shown to have varying effects, ranging from no effect to significant enhancement of clinical attachment. However, most studies have consistently shown that PRP results in more rapid healing, less postoperative pain, and less membrane exposure [4].

Growth factors and PRP will be described in greater detail in later chapters.

GBR in Maxillary Sinus Floor Elevation Surgery

Therapy through implantology has provided an alternative to edentulous patients. Alveolar bone loss associated with periodontitis and alveolar atrophy after tooth extraction in adults, which can result in pneumatization of the maxillary sinus, causes severe vertical and horizontal bone loss in the posterior maxilla [30]. Thus, the placement of dental implants in partially or totally edentulous posterior maxilla remains a challenging procedure owing to the small amount and poor quality of bone.

Although the use of short or tilted implants has been demonstrated to be a suitable therapeutic option, showing long-term biomechanical stability of prostheses, sinus grafting has emerged as a good option for facilitate implant placement. Maxillary sinus floor augmentation is the most frequently used method to increase the alveolar bone height of the posterior part of the maxilla. Several types of bone grafts have been studied and used for maxillary sinus floor augmentation.

Different grafting techniques have also been proposed; the lateral approach is the most commonly used technique [31]. Introduced by Tatum [32] and later modified [33,34], this approach accesses the maxillary sinus through the creation of a bone window in the lateral sinus with a round bur and maintains the sinus membrane intact; this structure is then elevated and mobilized with placement of the grafting materials [31].

Alternative techniques have also emerged, including elevation of the sinus membrane with a crestal approach using osteotomes, and the position is maintained by implants [32, 35, 36]. Lundgren et al. [37] showed that mere lifting of the sinus membrane without graft placement created a void space, allowing the formation of blood clots, resulting in late formation of new bone in accordance with the principles of GTR [31, 38, 39].

Based on these findings, Cricchio et al. [31] performed a study in 2011 in which they elevated the maxillary sinus membrane and realized the simultaneous insertion of titanium

implants without the use of any grafting material, as described by Lundgren et al. [37]. Thus, a bone window was created in the lateral wall of the sinus, and the bone flap was removed into saline solution. The sinus membrane was elevated in order to create a secluded compartment for the implants. After elevation of the membrane, the implant was positioned, and a twist drill was used for the final preparation of residual bone. The removed bone window was then repositioned and, if necessary, secured with the aid of cyanoacrylate tissue glue. Finally, the mucoperiosteal flap was reattached.

Of the 239 implants inserted, 50 were inserted entirely in residual bone, and the remaining 189 protruded into the maxillary sinus. Of these 189 implants, 179 protruded at least 4 mm in the created sinus compartment (mean: 8 mm, range: 4–13 mm). After 96 sinus membrane elevations, the authors suggested that mere elevation of the maxillary sinus membrane at the time of implant insertion may be a successful approach for bone reformation and implant survival, consistent with other studies [37, 40, 41–43].

Thus, Cricchio et al. [31] utilized the principles of GTR and GBR without utilization of the membrane. However, the bone flap, which was removed from the bone window, was used in a protective role.

When teeth are adjacent to the edentulous area, bone augmentation is required, and the procedure becomes more difficult. The antral membrane balloon elevation (AMBE) technique is useful in this area. This technique is realized with a limited incision, minimal mucoperiosteal flap reflection, and a small window, in which the membrane is elevated to the medial wall of the sinus cavity, avoiding sharp dissection around the roots of the adjacent teeth [44]. Thus, complications, such as morbidity, blood loss, long operative time, and postoperative pain, are reduced [44].

Solta and Smiler [45] described the AMBE technique. A crestal incision is made, extending the length of the edentulous area. Osteotomy of the buccal bone is performed, and the sinus membrane must be preserved. The resulting bony fenestration is gently pressed inward, carrying the underlying membrane along with it. The dissection should progress all the way to the medial wall of the sinus. A balloon of latex material is placed against the sinus floor midway between the lateral and medial walls and is gently inflated with 2–4 mL sterile saline. As it expands, the membrane is elevated. Thus, the fragile epithelium will be subjected to minimal trauma. The balloon is then deflated and removed. A resorbable collagen membrane is soaked with PRP and placed under the elevated sinus membrane. A grafting material can then be utilized and mixed with PRP. A second guided bone regenerative membrane is trimmed, moistened with PRP or aqueous antibiotic, and placed over the lateral wall window. The mucoperiosteal flap is repositioned and sutured [45].

Among the advantages already cited, such as elevation of the sinus membrane with minimal risk of tearing and reducing postoperative pain, bleeding, and infection, this technique can be completed within 30 min, as reported by Soltan and Smiler [45]. Thus, this technique, which uses elevation of the sinus membrane, placement of the grafting material with PRP, and membranes to guide regeneration, has become a highly successful and reliable procedure [45].

As described above, application of growth and differentiation factors can be used to enhance the wound healing process. Platelets produce and release PDGF, which enhances osteogenic differentiation and bone repair in fracture models and critical-sized calvaria defects [46–48]. Additionally, PDGF has a significant role in the wound healing process with the capacity to stimulate chemotaxis, cellular activation, and proliferation in fibroblasts and

osteoblast-like cells. Therefore, considerable interest has emerged because of the potential benefits of using PRP, a highly concentrated form of platelets.

In a case-series report, Kassolis et al. [48] described the use of PRP in combination with freeze-dried bone allografts (FDBAs) for alveolar ridge and maxillary sinus GBR procedures. The authors created full-partial thickness flaps that were elevated at both the sinus and the ridge augmentation sites, and the sinus cavity was exposed for graft insertion. Maxillary sinus grafting was accomplished using the Caldwell-Luc approach. The composite graft was a mixture of FDDBA and PRP, saturated with an autologous thrombin-rich extract. After the placement of the graft, coagulated PRP gel was used to cover the graft. Ridge augmentation sites required added flap mobilization and repositioning of the facial mucoperiosteum to permit passive primary closure over the FDDBA/PRP.

In all three cases, the authors observed new bone formation, where FDDBA particles were amalgamated with the newly forming bone. Consistent with previous studies [49], these data suggested that the use of PRP may allow for earlier implant placement and/or loading by stimulating and enhancing the wound healing process, including osseous regeneration. Bovine thrombin has been used to activate coagulation and precipitate gel formation.

One of the problems with the utilization of allografts is that osseous wound repair occurs more slowly than that with autogenous bone grafts. The degree of revascularization of bone allografts also appears to be slower than that with autogenous grafts. Utilization of these materials that may improve osseous wound repair following regenerative procedures using allografts, similar to the use of PRP. Thus, an alternative to autogenous bone grafting, which would require a second surgery for graft removal, would be allografts and PRP.

The use of bone inductive growth factors may enhance the development of mature lamellar bone, which could support dental implants sooner and more predictably. Recombinant human PDGF (rhPDGF-BB) has been shown to improve regeneration, as previously described in this chapter.

Urban et al. [50] demonstrated the successful use of rhPDGF-BB in conjunction with autogenous bone, anorganic bone mineral, and barrier membranes to reconstruct severe alveolar bone defects in the posterior maxilla. A patient with a history of dentoalveolar infection, several fistulous tracts, and advanced mobility showed advanced periodontal bone loss with associated periapical lesions upon radiographic examination. In this case, the teeth were extracted, and a severe vertical ridge defect was noted 2 months later.

After adequate incision, a rectangular antrostomy with rounded corners was created at the lateral wall of the maxillary sinus. The sinus window was infractured, and the sinus membrane was elevated with care to prevent perforations. The recipient bony bed was prepared with multiple decortical holes to expose the medullary space. Autogenous bone was harvested from the right ascending ramus, mixed with anorganic bone mineral, and hydrolyzed in rhPDGF-BB. The e-PTFE membrane was fixed on the palatal side, and the bone graft then was placed within the subantral space and appositionally on the vertical alveolar defect. The membrane was folded over onto the buccal alveolus and fixed with additional titanium pins.

The mesial border of the e-PTFE membrane was placed 4 mm from the distal surface of tooth and was unfilled for about 2 mm supracrestally. This area was filled with additional bone graft material, connecting the denuded root surface to the open end of the membrane. A resorbable collagen membrane was applied to protect and contain this area. An additional

collagen membrane was applied to cover the sinus window. Suturing was performed for tension-free primary closure.

Bone growth was evident over the membrane in the area where the resorbable collagen membrane was utilized. After removal of the titanium pins and the e-PTFE membrane, the authors observed complete vertical bone regeneration [50].

In another study [51], a 100% success rate was observed when placement surface implants were realized after vertical GBR. Thus, this treatment modality may allow bone harvesting to be avoided altogether.

GBR in Oro-Antral Communication (OAC)

The large volume of the maxillary sinus, which can be in close proximity with some tooth apices under certain circumstances, facilitates pathological communication between the oral cavity and the maxillary sinus, i.e., OAC, and this clinical complication is often encountered by oral surgeons [52]. The condition mostly follows dental extraction or endodontic treatment, and the intra-operative diagnosis of OAC is usually based on the Valsalva maneuver [53] or penetration of a blunt-edged Bowman probe to assess perforations of the maxillary sinus floor [54-56]. This can be contaminated by bacteria, resulting in infection, impaired healing, and chronic sinusitis. OAC may progress to the formation of oro-antral fistula (OAF), when the epithelium is involved [57]. Small fistulae tend to heal spontaneously after formation of blood clots and secondary healing [56], whereas larger fistulae rarely heal. Surgery is indicated if a fistula does not heal within 3 weeks [57], in order to avoid infection and fistula formation [56].

Many techniques have been proposed to resolve this condition. However, the selected technique should achieve both hard and soft tissue closure, repair OAC, and facilitate prosthetic rehabilitation through the placement of an endosseous implant [56]. Ogunsalu described this technique for the first time in 2005 [52].

The techniques described above have some limitations, including reduction in the depth of the vestibular sulcus, achievement of soft tissue closure only, requirement of bone grafting, and induction of severe pain and scarring in the palatal flaps.

Notably, the Bio-Oss-Bio-Gide Sandwich technique described by Ogunsalu [52] excludes all of the above limitations and has additional advantages of concurrent bone tissue regeneration, which will enable the later placement of an endosseous implant. Bio-Gide is a pure collagen membrane extracted from pigs and has a porous surface facing the bone, which allows the in-growth of bone-forming cells and the formation of a dense surface facing the soft tissue, which will prevent the in-growth of fibrous tissue into the bony defects. The membrane is made of type I and type III collagen and will resorb within 24 weeks. Additionally, Bio-Oss is a safe bone graft material processed from bovine sources with high similarity to human bone.

The technique utilizes sandwiches of Bio-Oss granules in Bio-Gide, which is sutured together at three sides. After insertion of the Bio-Oss, the fourth side is adequately closed using resorbable sutures, creating a closed sandwich. The sandwich has a smooth side oriented upwards and a rough side positioned to face the alveolar bone. The mucoperiosteal flap is raised, and the prepared sandwich is tucked into the OAC in such a way that it forms a convexity towards the sinus and a concavity towards the alveolar bone. Bio-Oss is added to

fill the concavity. The height of the alveolar ridge is substantially reduced at the site of the opening. Edges of the soft tissue to be approximated are prepared such that raw surfaces will be in contact with each other, and suturing is carried out without tension [52, 56].

In a case presented by Ogunsalu [52], after 8 months, a new maxillary sinus and subantral bone of good quality and height were created, permitting the placement of an endosseous implant. This sandwich technique at the closure of OAC is new and promising, without the need for donor site surgery, providing advantages in terms of time and cost. By using the membrane to isolate the bone tissue, this technique allows the formation of new bone tissue and achieves soft tissue closure [52].

After reporting of the Ogunsalu technique [52], Sandhya et al. [56] performed a study with 10 patients and a 6-month follow-up to investigate both soft and hard tissue closure of OACs with the use of resorbable GTR membranes and bone substitutes and application of human freeze-dried mineralized bone as grafting material. The authors did not observe significant immediate complications. Pain was present only in three patients, and swelling was present in four patients; these side effects gradually subsided by the end of day 7. Epistaxis was observed in one patient on day 1 postoperation. Delayed complications were not observed, and there was no evidence of infection, wound gaping, fistula formation, loss of graft, or sinusitis. An average bone formation of 11.84 mm was observed after 6 months, and the average width was 6.9 mm. In relation to the quality of bone formation, by the end of the 6-month follow-up, seven patients showed trabeculae indistinguishable from the adjacent bone [56].

Ogunsalu et al. first used this technique in 2000 [58], and in their classic papers, the authors suggested other possible applications of this technique to include reconstruction of the orbital floor, closure of oro-antral fistula, reconstruction of bony cleft defects, and mastoid ablation [56, 58].

GBR in Treatment for Alveolar Cleft

One of the most common congenital anomalies is orofacial clefts, with a prevalence of 1:1000 and 0.4:1000 for complete unilateral and bilateral cleft lip and palate, respectively [59]. Patients with this deformity require multiple surgical procedures over long periods by multiple specialists in various fields [60]. The patients must undergo surgery to balance functional and esthetic outcomes against the potential increased restriction of normal maxillary growth and development [61].

The final aim is to rehabilitate these patients with missing teeth using dental endosseous implants, which requires adequate alveolar bone volume at the appropriate anatomic position [60].

Currently, the standard treatment for alveolar cleft repair is grafting with autogenous bone [60]. Although other sources of autogenous bone have been attempted, autogenous bone grafting from the ilium is considered the gold standard [59] owing to its abundance and ease of access [61].

However, this site can produce a considerable degree of postoperative morbidity, including persistent pain, prolonged recovery time, hemorrhage, scarring, and lesions of the lateral femoral cutaneous nerve [59]. In addition, iliac crest bone grafting has been shown to result in total mean volume losses of 43.1% [62] and 49.5% [63] at approximately 1 year after

the secondary alveolar cleft repair. This resorption may prevent successful placement of endosseous implants without further grafting [60].

Thus, Le and Woo [60] reported the successful utilization of mineralized human allografts to treat two adult patients with severe alveolar cleft defects using a GBR technique. The treatment consisted of completely exposing the cleft defect. In case 1, in which the patients had a congenital unilateral cleft palate and large fistula on the buccal vestibule of the area around the alveolar cleft site extending into her right nostril, the nasal layer was closed primarily by suturing, and a resorbable collagen membrane was placed to reinforce the recreated nasal lining; mineralized human allograft material mixed with the patient's blood was then placed into the cleft defect.

In case 2, a patient with a congenital cleft lip underwent multiple previous surgeries, including alveolar cleft repair with iliac crest bone grafting. Panoramic radiographs and computed tomography scanning showed a large alveolar defect at the site of the missing incisor, making it unsuitable for implant placement. Mineralized human allograft material mixed with a BMP-soaked collagen sponge and the patient's blood was then placed into the cleft defect. A resorbable collagen membrane was placed over the graft material, and in both cases, the oral mucosal layer was closed in a tension-free manner. Re-entry at 5 months was realized and showed dense bone where the graft was placed, with later placement of the endosteal implant. After 3 months, good osseointegration was noted, and the alveolar bone height and width remained stable.

Thus, the repairs were accomplished with a GBR technique without the use of autogenous bone, suggesting potential applications in the treatment of patients with alveolar clefts defects, without the need for iliac crest bone grafting and associated morbidities.

Bone grafting of the residual alveolar cleft is now a well-established technique. However, Kawata et al. [64] reported the closure of an alveolar bony defect without bone grafting, using a nonabsorbable membrane.

A patient with unilateral and nonsyndromic cleft lip or palate on the left side had late mixed dentition with good soft tissue closure. The upper left permanent canine was present, adjacent to a narrow bony cleft at the height of the apex of the neighboring central incisor. The oronasal fistula was excised, and the alveolar cleft was completely exposed. Subsequently, the nasal mucosa was carefully dissected from the oral mucosa, sutured, and pushed upwards into the nasal cavity. An e-PTFE nonabsorbable membrane barrier was placed to cover the bony defect. The membrane was pushed under the periosteum and secured passively at the base of the flaps. The flaps were then repositioned and sutured to cover totally the membrane. Four months after surgery, radiographs showed a bony bridge and closure of the alveolar cleft. This was the first study to evaluate the use of GBR with a nonabsorbable membrane to close the alveolar cleft when the bony cleft was large and lacked bone support, indicating the requirement for the supporting membrane [64].

GBR in Reconstruction of Defects after Tumor Resection

GBR can also be used to reconstruct bone defects after tumor resection. Reconstruction of these defects represents a challenge in head and neck reconstructive surgery.

Vitkus and Meltzer [65] described a patient with adenomatoid odontogenic tumor (AOT) combined with calcifying epithelial odontogenic tumor (CEOT); this presentation was

referred to as combined epithelial odontogenic tumor. Approximately 1 year after surgery for removal of an impacted canine, the patient presented with an erupted maxillary left canine with an asymptomatic firm, red swelling circumscribing the buccal and palatal aspects of the tooth and extending from the keratinized tissue to the mucosa. Intra-oral radiographs revealed a well-circumscribed radiolucency superimposed on the entire root. Buccal and palatal flaps were raised, exposing a cystic-type lesion that was easily removed and leaving a large cavity exposing the root just short of the apex. A thin layer of bone covering the root surface was found, with large vertical defects interproximally. To prevent the ultimate destruction of the tooth, a graft of demineralized freeze-dried bone was placed in the cavity and covered with a nonresorbable barrier membrane made of e-PTFE. Eight weeks later, the membrane was removed, and an intra-oral radiograph showed trabecular bone.

The literature suggests that only the lesion should be surgically excised, with little mention of whether this will result in complete regeneration of the bone and how long this process will take. However, it is unclear whether complete regeneration will occur given the large bone loss, and it is expected that even partial regeneration will take considerable time. Despite this, the choice of GTR with freeze-dried bone grafting was made in an attempt to increase the predictability of the result.

Thus, the results showed that GTR combined with bone grafting could be used to aid in the rapid filling of large defects surrounding the teeth, created after surgical removal of the odontogenic tumors.

The quantity of bone available for harvesting may be insufficient for larger defects. rhBMP-2 is an osteoinductive growth factor that reduces the need for autogenous bone grafts. To date, studies of the use of rhBMP-2 for maxillofacial reconstruction have been promising [18].

Cicciu et al. [18] investigated the clinical and radiographic long-term results of a hemimandibular reconstruction using rhBMP-2, an absorbable collagen sponge, and titanium mesh. The patient in this case presented a large tissue mass and extension in the left mandibular region, with ominous growth; this lesion was diagnosed as a dentinogenic ghost cell tumor. The decision was made to manage the local tumor with en bloc resection and immediate reconstruction using an inferior titanium plate in order to maintain the mandibular soft tissue space. This process was carried out using an incision that extended into the bone and subperiosteal dissection to expose the entire defect. Subsequently, a mesh was placed to correct the defect. The underlying ridge was pierced to stimulate bleeding, allowing faster integration of the graft and supplying stem cells to the area. The rhBMP-2 was added to the absorbable collagen sponge, and a portion of the sponge was then cut into small pieces, mixed with the bone allograft, and placed into the titanium mesh. The titanium plate was subjected to maxillomandibular fixation and locked with the inferior plate for mandibular reconstruction.

After 3 or 4 months, the patient exhibited radiographic evidence of bone formation, and mandibular continuity was regained, as demonstrated both clinically and radiographically. After 9 months, the titanium mesh was removed, and dental implants were placed in position. Despite the extent of bone formation, the titanium remained inside the defect. The process of induced bone formation is a controlled response to highly concentrated levels of rhBMP-2.

Thus, the use of rhBMP-2, an osteoinductive agent, and allografts, which are osteoconductive, can enhance the amount and rate of bone formation [18].

GBR in Ridge Augmentation in Defects after Tooth Extraction

Vertical and horizontal alveolar ridge augmentation utilizing GBR has become a significant treatment option to provide optimal bone support for placement of osseointegrated dental implants. Vertical bone defects are more complicated to handle because of their high technical sensitivity [66].

In 1994, Simion et al. [67] performed a study in which the patients received conical Brånemark-type implants in sites requiring vertical augmentation. The implants protruded 4–7 mm from the bone crest, and titanium miniscrews were positioned distally to the implants, protruding 3–4 mm from the bone level. Both were covered with a titanium-reinforced membrane, and the flaps were sutured. After 9 months, the membranes were removed. There was a gain in bone height from 3–4 mm, and the implants were in direct contact with bone.

In a retrospective study in 1998, Tinti and Benfenati [68] evaluated the predictability of obtaining a vertical ridge augmentation around dental implants following GTR principles. The authors observed that when the clinical protocol was accurately followed, the possibility of clinical complications was reduced, and the results for achieving vertical ridge augmentation around implants were predictable.

Implants are often removed due to placement in unfavorable positions. Incorrect positioning of implants may result in biomechanical problems, loosening, and/or fracturing of the cover screws, implants, or implant collars in addition to occlusal discrepancies and compromised aesthetics and speech [69].

An ideal bone tissue volume is required for proper implant placement. Bone resorption will occur secondary to tooth extraction, mainly when multiple teeth are extracted at the same time. Among various ridge expansion techniques, GTR for the treatment of ridge deficiencies is considered a safe and predictable treatment modality [70, 71].

Using this method, Toscano et al. [69] analyzed 73 consecutively treated lateral ridge augmentations that used composite material of demineralized freeze-dried allografts, mineralized cortical cancellous chips, and a biologically degradable thermoplastic carrier combined with a resorbable membrane for GBR in partial or completely edentate patients. An incision was made to the palate or lingual of the treatment site and was extended at least one tooth beyond in the mesial and distal directions. The periosteal was then released to allow for tension-free closure of the flap over the membrane and graft. Measurements of the pre-augmentation ridge width were made, and the bone defect was frayed to enhance revascularization of the site. The membrane was trimmed to fit the site and was applied to the thermoplastic composite graft. The graft was covered with the pretrimmed resorbable collagen membrane, and tension-free closure was performed. All cases were allowed to heal for a minimum of 6 months before implants were placed, and a second measurement was performed close to where the first measurement was made.

Researchers observed that the average presurgical ridge width was 4 mm. During stage I implant placement, an average ridge width postaugmentation of 7.5 mm was achieved, and the average gain in horizontal ridge width was 3.5 mm (range, 3–6 mm).

In 2012, Kao et al. [66] used a GBR technique and obtained satisfactory results for the edentulous area with severe bone loss. The patient suffered from advanced periodontitis of teeth 36, 37, and 47. Periapical radiographs revealed severe alveolar bone loss around teeth 36 and 37, which were subsequently extracted.

The GBR procedure was then performed. The flaps were elevated to expose the atrophic ridge and the immature healing sockets, and evident vertical and horizontal bone defects were found. The bleeding process was promoted, and two tenting screws were positioned. Autogenous bone was harvested from the mandibular ramus and mixed with FDBA particles. The Ti-reinforced e-PTFE membrane (TR6Y) was shaped for perfect adaptation and fixed to the lingual and buccal regions. The soft tissue was secured with nonresorbable horizontal mattress sutures and interrupted sutures. Six months later, the second surgery was performed to remove the nonresorbable membrane, and the site revealed regenerated hard tissue covering the surface of the tenting screws.

The authors concluded that GBR with the Ti-reinforced e-PTFE membrane, tenting screws, and bone grafts offered predictable functional reconstruction of large vertical defects [66].

Studies in Animals

Kostopoulos et al. [72] conducted an interesting study in rats that has had a major clinical impact on cranial and maxillofacial surgery. They created bone increases equivalent to 5–6 times the original width of the mandibular ramus. The study involved exposure of the mandibular ramus; on the test side, the periosteum was left covering the lateral surface of the ramus, and on the other side (control), the periosteum was elevated together with the flap. A Teflon capsule was then placed to face the periosteum or the bone surface with the open part before the closure of the wound. At 120 days, the mean amount of bone obtained in the test specimens was 56%, reaching up to 52% in controls. These findings indicated that a secluded space created by an occlusive barrier adjacent to existing bone or periosteum may be filled with bone tissue.

This enabled GBR to be performed as an alternative method when it was necessary to obtain bone autografts from patients without sites having adequate amounts of donor bone.

In 1995, Bosch et al. [73] aimed to investigate the amount of bone formed in defects created experimentally in bone parietal. They protected the bone with one or two e-PTFE membranes in 29 Wistar rats, which were divided into two groups. In the double membrane group, the left experimental bone defect was protected by an outer e-PTFE membrane under the periosteum and parietal muscles and an inner membrane between the dura mater and the parietal bone. In the single membrane group, only the outer membrane was placed.

From this analysis, the authors observed that in the majority of specimens in the group in which only one membrane was used, the experimental site did not regenerate. In contrast, in the group with the double membrane, the majority of experimental defects had complete closure of the bone. These data demonstrated the importance of the separation of bone tissue and muscle tissue to obtain correct regeneration.

In 1997, Hurzeler et al. [74] extracted the maxillary canines and lateral incisors from eight rhesus monkeys. After a healing period and soft tissue expansion, implants were placed in the atrophic ridge on each side in such a way that its coronal 4–5 mm remained circumferentially exposed above the bone level. Two types of membranes were tested for implantation: 1) a bioresorbable barrier made of D,L-lactid-co-trimethylencarbonate (poly membrane) and 2) a nonresorbable e-PTFE barrier.

The results showed that the mean bone-to-implant contact length fraction was 32% of the total implant length with the polymembrane and 58% with e-PTFE, which exhibited significantly greater bone filling capacity than the polymembrane. Histologic observations of polymembrane specimens demonstrated a moderate inflammatory reaction related to the degradation and resorption products of the barrier. In conclusion, the nonresorbable e-PTFE GBR barrier was found to be superior to the bioresorbable barriers tested in the present investigation.

Li et al. [75] investigated the effects of guided bony regeneration using collagen membranes for sinus augmentation in the first maxillary molars of 18 adult female beagle dogs. After extraction of teeth, the sinus floors were lifted, and the implants were placed. A combination of autografts and Bio-Oss was used as a grafting material. The collagen membrane was folded at the lateral osteotomy window, at the apex of the implants, and at a certain part of the palatal bone. As a control group, the opposite site received a collagen membrane covering the osteotomy window. From the results, the authors observed grafted materials without resorption or subsidence on the experimental side, with new bone formation at the apex of the implants. On the control side, the grafted materials were shifted and absorbed. Histological examination showed increased formation of new bone in the experimental group, and this new bone matured over time. This study showed that the presence of the membrane facilitated bone regeneration on the apical surface of the implants and that the only sinus membrane could not effectively stimulate formation of new bone in sinus augmentation.

Many materials have been studied for bone regeneration. The best results are found with utilization fresh autogenous materials due to its capacity for osteoinduction and osteoconduction. However, there are some disadvantages, as already discussed, such as pain and edema caused by additional injury to the donor site, the limited volume of bone tissue that can be harvested, and high graft-fragment resorption [76, 77]. Thus, other materials, such as allogeneic bone graft materials, which do not have bone regenerative capacity but do not require an additional donor site, have been used for bone grafting.

Using this method, Ahn et al. [78] evaluated bone formation after the use of allogeneic bone, with or without utilization of a membrane, in rats. The materials used in the experiment were the allograft Tutoplast Spongiosa Microchip, mineralized cancellous bone allografts (MCBAs), and absorbable membranes made from human pericardium and collagen. A 2-cm incision was made from the occipital bone to the frontal bone, and subcutaneous tissues were elevated together with the periosteum. A full-thickness defect area approximately 8 mm in diameter was then created. The control group was sutured without addition of graft material or the membrane. In group 1, the Tutoplast was transplanted into the area and sutured in place by closing the periosteum. In experimental group 2, the Tutoplast was transplanted into the defect area, covered with pericardium attached tightly to graft materials, and sutured by closing the periosteum.

In the control group, most areas were filled with loose connective tissue. In group 1 (allogeneic bone), bone from new bony spurs and host bone were observed on the edge of the defect area, with abundant proliferation of blood vessels and features of active bone formation. All animals showed immature bone formation in the center of the defect area and exhibited delayed bone fusion. In group 2 (allogeneic bone and absorbable barrier membrane graft), within 6 weeks, the membranes were partially absorbed, and numerous inflammatory cells were present. At week 12, the membrane boundary had disappeared in several areas, indicating that membrane absorption had progressed substantially, and the center defect area

was connected with the rim area and proliferated continuously. A bone-filling pattern was observed at the center of the defect area, and connective tissues were hardly detected.

Utilization of membranes is essential for osteoinductive regeneration. Membranes that are not degradable require a second surgery, which can be harmful to growing granular tissue. Thus, the use of absorbable membranes is recommended. As described by Ahn et al. [78], membranes inhibit connective tissue invasion, thereby facilitating new bone formation. Inflammation that occurs around the absorbable collagen barrier membrane is associated with degradation, as observed by Ahn et al. [78], and inflammatory cell infiltration was found to be restricted to the membrane rim and to not significantly affect bone regeneration [78].

Theoretically, the ideal bone substitute should have osteoconductive characteristics by acting as an intermediate-phase scaffold to give support during bone healing and osteoinductive characteristics by working as a guide to stimulate bone growth before being gradually replaced by the newly formed bone [79].

Deproteinized bovine bone mineral (DBBM) is an inorganic bovine bone derivative with a mineral content comparable to that of human bone, allowing integration of the material into bone. In addition to osteoconductive mechanisms, studies have suggested that this material may also trigger osteoinductive mechanisms [79].

Bioactive ions can also have favorable effects on the bone response during healing. Calcium sulfate (CaS) is a common bone substitute that is highly biocompatible and osteoconductive and undergoes virtually complete resorption *in vivo* [79, 80].

Turri and Danlin [79] evaluated the potential biological differences of a synthetic bone substitute material characterized by a high dissolution rate and release of high concentrations of ions in the wound area (CaS) with an osteoconductive material (DBBM) with a barrier membrane acting as control, in the GBR setting.

The CaS and DBBM particles were placed in defects created in the edentulous space between the incisors and molars in the maxilla of rabbits, with or without placement of a membrane. After 2 weeks, total resorption of the CaS material was observed, regardless of the presence of a barrier membrane, and minor resorption was observed for the DBBM particles. Because of deproteinization, bone resorption was blocked by osteoclasts [81]. The CaS group showed more bone regeneration than the DBBM group. Moreover, the addition of an ECM membrane had substantial effects on bone regeneration owing to stimulation of angiogenesis in the early healing process [79].

UNIT 4 - GTR IN ORAL SOFT TISSUE

Oral mucosal defects are often an inevitable consequence of tumor excision. Recently, great progress has been made in reconstructive surgery for large soft-tissue defects in the oral cavity, resulting in increased survival rates in patients [82].

In small oral tissue defects, the use of palatal or buccal mucosal autografts or muscle may be appropriate [82, 83]. However, for reconstruction of large soft-tissue defects, cutaneous or myocutaneous flaps are needed [82].

Autologous skin grafts have been employed in animal and human studies; however, these grafts seem to maintain their original characteristics, such as hair growth, and are associated with donor-site morbidity [83]. Moreover, skin flaps are less flexible than the mucosa of the

oral cavity and are inadequate for restoration of oral functions, such as speech, mastication, or swallowing [82]. Additionally, the use of skin flaps is associated with problems of cosmetic appearance. For example, the color and texture of the skin are not completely consistent with the tissues of the oral cavity [84]. Scar formation at the donor site may also occur, often necessitating secondary operations [82]. Thus, it is advisable to reconstruct intra-oral soft-tissue defects with soft tissues from the mucosa.

Wada et al. [82] described a procedure called biological-guided mucosa regeneration (BGM^R). Based on the results of animal experiments and epithelialization of the grafted myofascia in the oral cavity, various myofascial graft materials have been applied for reconstruction of intra-oral soft-tissue defects, thereby restoring nearly normal mucosa. This mucosal tissue shows good mobility of the intra-oral organs, as opposed to the more rigid and less flexible skin tissue.

The authors grafted myofascial flaps without skin in patients with oral defects caused by tumor resection in the tongue, buccal mucosal, lower gingival, floor of the mouth, and/or oropharynx.

The myofascial flap was tunneled up and inserted into defect in such a way that the fascial surface was oriented to face the oral cavity, and the myofascial flap was tightly sutured to the surrounding incised mucosal margin, resulting in a yellowish fibrin membrane on the surface.

Based on this clinical experience, using platysma myofascial flaps or pectoralis major myofascial flaps, the authors observed favorable progression of mucosal regeneration, with gradual epithelialization along the immature granulated myofascial and without clinical evidence of infection on the bare granulated myofascial. This method was useful for reconstruction of the inferior half of the oral cavity, including the oropharynx.

In summary, the authors presented a procedure for myofascial grafting that served as an alternative for the reconstruction of intra-oral soft tissue defects based on GTR principles.

Among the biomaterials employed by maxillofacial surgeons, those derived from animals are widely used; for example, catgut tissues are still popular. Collagen materials are also commonly used and are available in various forms, including laminates, sheets, fabrics, gels, and powders, and have been used as dressings for ulcers and burns and for induction of bone formation [84].

Rastogi et al. [84] utilized xenogenous, crosslinked collagen sheets as a cover for wounds in the oral cavity after excision of premalignant lesions, benign lesions, reactive proliferation, and incisional biopsy wounds in 60 patients. The collagen membrane showed good conformability, granulation, and epithelialization in most cases.

Wounds that are left uncovered in the oral cavity are prone to infection. Grafted wounds are known to heal faster than open wounds. The best solution may be mucosal grafts; however, materials for these grafts are not sufficiently abundant. Although skin grafts may be the next-best solution, the disadvantages of these grafts have already been discussed.

In the study by Rastogi et al. [84], the collagen membranes slowly underwent collagenolysis and were sloughed off over time, allowing changes to occur in granulation tissues, which appeared to be clinically healthy and uniform. The adherence of the collagen membrane may be a result of the interaction between fibrin and collagen, but was most likely a result of fibrovascular ingrowth into the collagen membrane.

The collagen membrane exhibited minimal growth of granulation tissue and no major infection, thus supporting its use as a temporary biological dressing material in the oral cavity

devoid of the mucous membrane. Accordingly, this material is an alternative to autologous grafts and a satisfactory addition to the armamentarium of oral surgeons as an excellent wound graft material [84].

UNIT 5 – FINAL CONSIDERATIONS

Based on the limited capacity of current strategies to reproduce tissues damaged by trauma, disease, anatomical or congenital defects, or tumors, surgeons have attempted to identify alternatives to tissue engineering approaches. Thus, tissue engineering strategies have been developed to facilitate reproduction of various body tissues.

However, when considering the craniofacial region, these approaches are more complex and challenging.

Today, GTR, a subfield within tissue engineering, is a reality and has been shown to be a very promising approach. The use of barriers to protect the tissue and select desirable cells to facilitate tissue regeneration, the presence of scaffolds, the use of growth factors, and the biocompatibility of tissue grafts have made the development of effective grafts that can restore lost tissue more achievable.

In dentistry, the utilization of GTR has been reported in surgery for maxillary sinus floor elevation, ridge augmentation for implant planning, correction of OAC, reconstruction of defects after tumor resection, and treatment of alveolar cleft, among other applications.

Although GTR still needs to be more established in osseous tissues, this method, similar to GBR, should also be applicable in other tissues, including the oral mucosa, thereby contributing to successful tissue engineering.

Advances in GTR have expanded the range of treatment possibilities, allowing us to achieve the regeneration of ideal, well-formed, functional tissues; this approach should be studied in great detail in order to improve the potential success and applications of GTR-based therapies.

Chapter 116

HOW TO PREVENT ORTHOPEDIC COMPLICATIONS AND EARLY SURGERY IN CP CHILDREN: ROLE OF BOTULINUM TOXIN THERAPY

***Vera Zmanovskaya^{1,*}, MD, PhD, Elena Levitina², MD, PhD
and Svetlana Ushakova², MD, PhD***

¹Children's psychoneurological medical rehabilitation center "Nadezhda",
Tyumen, Russia

²Tyumen state medical university, Tyumen, Russia

ABSTRACT

Short-term effects of multilevel Botulinum Toxin therapy allow to reduce muscle spasticity and thereby ensure optimal conditions for motor functions recovery in children with cerebral palsy (CP), delay the onset of secondary orthopedic complications and postpone orthopedic surgery. Multiple injections of botulinum toxin type A in combination with rehabilitation measures reduce the need in surgery comparing to rehabilitation without Botulinum Toxin therapy. Multilevel Botulinum Toxin therapy provides control postoperative pain syndrome, reduces the time to start functional rehabilitation in postoperative period, including standing with weight-bearing and encourages CP patients to recover the activity temporarily reduced after surgery.

Keywords: cerebral palsy, spasticity, botulinum toxin type A, multilevel Botulinum Toxin therapy

1. ROLE OF LONG-TERM BOTULINUM TOXIN THERAPY IN PREVENTION OF SECONDARY ORTHOPEDIC COMPLICATIONS IN CEREBRAL PALSY

Introduction

Despite a great variety of methods of non-surgical treatment in cerebral palsy, the occurrence of contractures and skeletal deformities is significant in CP children. Disproportional length of the tendomuscular complex relative to the growth of the corresponding bone segments as well as muscle retraction caused by long-term existing spasticity are considered important elements for pathogenesis of articular contractures, limb deformities, joint dislocations and other secondary orthopedic complications [1-5]. Botulinum neurotoxin type A (BoNT-A) is used as part of the basic therapy in CP patients for over 25 years. In literature, temporary improvements following Botulinum Toxin therapy such as increased range of motion at joints, muscle tone reduction, muscle lengthening and improved gait pattern have been reported [6-9]. Although short-term effects of Botulinum Toxin therapy are recognized, data about sustained functional disease-modifying effects of the therapy and role of Botulinum Toxin therapy in term of prevention of orthopedic complications still remain controversial and insufficient [4, 10, 11].

Objective of our prospective study was to assess the efficacy of multiple injections of BoNT-A (Dysport®) as part of the complex rehabilitation program of children with spastic cerebral palsy in prevention of secondary orthopedic disorders.

Material and Methods

This prospective study included 86 children with spastic CP aged from 2 to 13 years at the beginning of treatment followed during the period from 2001 to 2012. All children were ambulant, classified as level I-III according to the Gross Motor Function Classification System (GMFCS). Criteria of inclusion were muscular spasticity of (1+) or more measured by Ashworth scale; no previous injections of botulinum neurotoxin A (Dysport®). Patients should not have fixed contractures.

Patients were divided into two groups. The group 1 included 45 children (21 girls and 24 boys, mean age of 4.8 ± 1.8 years) who received 8 consecutive injections of Dysport® a part of the complex rehabilitation program. The group 2 included 41 CP children (19 girls and 22 boys, mean age of 5.1 ± 2.2 years) who underwent a similar complex treatment but without BoNT-A injections due to parents' refusal. There were no statistically significant differences between the groups in gender, age and motor development according to the GMFCS.

In group 1, the children received multilevel injections of Dysport® at least in 24-week intervals. Dysport® was administered with calculated dose of 14 to 30 U/kg, the average dose being 26 ± 4 U/kg. Follow-up controls after injections were performed in 2, 6, 10, 16 and 24 weeks.

Physical and neurological examinations including Modified Ashworth Scale for Grading Spasticity, goniometric measurements of the active and passive range of motion in adjacent joints, assessment of active ROM with the selective motor control scale, and assessment of

the gait pattern (using initial foot contact subscale of the Physician's Rating Scale) were carried out on all subjects in both groups every 6 months during two following years.

The statistical values described the mean and standard deviation. The Modified Ashworth Scale data were compared by using Wilcoxon signed-ranks test for independent samples. The test was two-tailed with a 0.05 level of significance. The chi-square test determined the significance of differences in the cases with indications for surgical treatment. This research was approved by the Review Board of our institution. The study complies with the Declaration of Helsinki statement on medical protocol and ethics. Representatives of all patients enrolled in the study provided oral and written informed consent.

Results

In group 1, the significantly reduced muscle tone assessed by Ashworth scale was revealed in follow-up period after multilevel Dysport® injections. The muscle spasticity didn't return to initial values during 24 weeks after the first four multilevel procedures. The difference remained statistically significant. The decrease of spasticity after following multilevel injections (the 5th-8th procedures) were also noticed but the difference was no more significant in comparison to the initial values.

Follow-up of the subjects from both treatment groups over a 24 months' period revealed a tendency to a fewer number of cases who required surgical treatment of orthopedic complications after 4 consecutive injections of Dysport® in the BoNT-A group (Table 1).

In 48 months after beginning of treatment, the difference in occurrence of orthopedic complications requiring surgical intervention became significant between the groups (Table 2). In group 1 only 21 patients (47%) developed orthopedic complications justifying surgery, the occurrence of secondary orthopedic disorders surgery was significantly higher in group 2 (without BoNT-A injections): 29 patients (71%).

Table 1. Number of children with orthopedic complications required surgery in 24 months after beginning of the study

	Group 1	Group 2	P
Numbers of children with indications for orthopedic surgery, n (%)	18 (40)	18 (45)	p = 0.883

Table 2. Number of children with orthopedic complications required surgery in 48 months after beginning of study

	Group 1	Group 2	P
Numbers of children with indications for orthopedic surgery, n (%)	21 (47)	29 (71)	p = 0.041

Thus, our findings demonstrated that repeated BoNT-A injections in association with complex rehabilitation program ensure a reduced occurrence of the secondary orthopedic complications requiring surgery in long-term follow-up.

2. ROLE OF BOTULINUM TOXIN THERAPY IN PREVENTION OF EARLY-AGE AND REPEATED SURGERIES IN CP CHILDREN

Introduction

Actual evidence-based approaches emphasize that the surgical interventions to address orthopedic complications and to correct the gait pattern should be delayed till secondary orthopedic problems occur. Generally, the age of the first orthopedic surgery varies from 7 to 14 years in patients with GMFCS I-III [12-14]. The modern concept of surgical orthopedic treatment in CP children implies a single-event multilevel surgery (SEMLS) aimed to manage all orthopedic issues and followed with a rehabilitation period for both lower limbs [1, 5]. Surgeries performed at early age have high risk of failure and relapses with less predictable final outcomes [15].

The objective of this comparative study was to evaluate effectiveness of multilevel Botulinum Toxin therapy on age of the first orthopedic surgery and on the recurrence rate of orthopedic disorders in postoperative period.

Material and Methods

The study has been performed during the period 2001 to 2017. It involved 149 CP children (78 boys and 71 girls aged from 2 to 14 years). All patients were classified as level II-IV according to the GMFCS.

The group 1 included 108 children with spastic CP who received injections of Dysport® as a part of their rehabilitation treatment. The group 2 included 41 children without BoNT-A treatment. Patients of both groups followed kinesiotherapy, complex physiotherapy and orthotics.

The multilevel surgeries when indicated have been performed in the Russian Ilizarov Scientific Center for Restorative Traumatology and Orthopedics. Postoperative follow-up with rehabilitation was ensured in Tyumen Children Psychoneurological Rehabilitation Center “Nadezhda”. Extensive rehabilitation treatment was performed during 1.5 months with interval of 6 to 8 weeks between courses for all children.

We assessed the age of the first surgical intervention and the incidence of repeated orthopedic operations in children included in the study.

Results

In group 1 (BoNT-A) the mean age, when indications for orthopedic surgery were revealed, was 10.5 ± 2.8 years (range: 8 years 4 months to 13 years). Only 5 children (4.6%) from this group had orthopedic disorder recurrence and underwent repeated surgery required a reoperation after the age of 14 years.

In the group 2 (without BoNT-A) the first surgery was done much earlier with mean age of 6.7 ± 2.1 years (range: 5 years 8 months to 9 years 2 months). The worsening of the gait parameters was observed in 95% (39 children) in the group 2 throughout pubertal growth

spurt. Thus, the recurrence of orthopedic complications resulted in repeated surgery in these children.

Finally, multilevel injections of BoNT-A in combination with complex rehabilitation and orthotics can postpone an orthopedic surgery avoiding high risks of orthopedic disorder recurrence during pubertal growth spurt. This strategy resulted in 4.6% orthopedic complication recurrence in patients following Botulinum Toxin therapy in contrast to 95% recurrence in children without BoNT-A injections.

3. MULTILEVEL BOTULINUM TOXIN THERAPY IN THE PAIN MANAGEMENT IN POSTOPERATIVE PERIOD IN CP CHILDREN

Introduction

The success of any surgical intervention depends on how early rehabilitation is started and how extensive it is. An active participation of a CP patient in the rehabilitation program for motor function recovery is crucial [16, 17]. But pain syndrome can interfere with comprehensive rehabilitation [18, 19]. Our study aimed to assess the effects of multilevel Botulinum Toxin therapy for pain management in early postoperative period following multilevel orthopedic surgery in CP children.

Material and Methods

We followed 55 GMFCS II-IV level CP children (29 boys and 26 girls) who underwent a single-event multilevel surgery. The children were aged from 5 to 17 years (mean age: 11.9 ± 2.5 years). The surgery was done in the Russian Ilizarov Scientific Center for Restorative Traumatology and Orthopedics. The rehabilitation program that included multilevel Botulinum Toxin therapy in all patients was performed in Children's psychoneurological medical rehabilitation center "Nadezhda" (Tyumen, Russia) during 1.5 months with interval of 6 to 8 weeks between courses for all children.

The early rehabilitation techniques included verticalization with total weight-bearing since the 14th-21st postoperative day, passive and active mobilization of joints since the 7th-14th postoperative day. After plaster cast removal, rehabilitation consisted of massage, strengthening exercises, posture management, muscle stretching, bracing, electric stimulation of weakened or impaired muscle groups.

In addition, injections of Dysport® were done in period of 2-3 months postoperatively depending on the muscle strength recovery, degree of spasticity and pain syndrome. In particular, after varus derotation femoral osteotomy, distal extension femoral osteotomy, various soft-tissue releases, distal rectus tendon transfer, children could complain on the pain syndrome in related anatomic zones during passive joint mobilization. The targets of Botulinum Toxin therapy were medial hamstring muscles, m.gracilis, m. adductor brevis, m. adductor longus, m. adductor magnus, m.rectus femoris.

After Grice procedure, calf-lengthening procedures, foot arthrodeses, tibial tendon transfers transplantation the pain was caused by passive motion such as knee extension and

ankle plantarflexion and dorsiflexion. The pain was localized in the popliteal region and along the posterior surface of lower leg. Thus, the targets of Botulinum Toxin therapy were caput mediale m.gastrocnemii, mm. tibialis posterior et anterior.

The pain severity in pre- and postoperative period was assessed using an adapted for children visual scale. A child was asked to point out the face whose expression was most closely corresponding to severity of the pain in particular moment of passive motion.

Results

In total, 74 surgical multilevel interventions were performed. There were 36 simultaneous bilateral surgeries and 19 consecutive interventions with mean interval of 29.4 days.

In mid-postoperative period CP patients received injections of botulinum neurotoxin type A (Dysport®) with total dose varied from 100 to 380 U (from 4 to 15 U/kg). The dose was calculated on base of body weight, then calculated dose was distributed between target-muscles. In details, 48 injections were done in adductors, 12 injections - in the rectus muscle, 14 injections - in m.iliopsoas, 48 injections – in muscles of medial hamstring group, and 18 injection in the ankle flexors and extensors (Table 3).

Table 3. Total and calculated Dysport® doses given to operated ICP children

Study group, n = 55

M ± SD	5.8 ± 4
Me (25; 75)	6 (3; 11)
min ÷ max	1 ÷ 12

The postoperative Botulinum Toxin therapy ensured reduction of pain score from 8.6 ± 1.2 to 4.3 ± 1.1 ($p < 0.001$) and provided favorable conditions for complex rehabilitation program.

So, SEMLS implies the use of appropriate techniques permitting early passive and active joint mobilization for ROM recovery. But the pain syndrome can interfere with rehabilitation program. Our approach with low dose injections of BoNT-A allows to reduce muscle pain significantly and thereby to improve conditions for rehabilitation program fulfillment.

DISCUSSION

Long-lasting spasticity in CP children results in muscle contractures, impaired motor abilities, pathologic gait patterns, posture disorders, and other secondary orthopedic issues [6, 20]. The injections of BoNT-A in spastic muscles have important role in spasticity reduction and orthopedic complication prevention [11, 21-24]. Therefore, Botulinum Toxin therapy ensures a double advantage to CP patients: 1) reduction of increased muscle tone and improvement of motor control; 2) stretching of muscle due to reduced spasticity that allows their longitudinal growth along the spontaneous growth of bones [6, 10]. The use of botulinum neurotoxin A in clinical practice has been ever increased over the last years and currently Botulinum Toxin therapy is recognized obligatory technique in management of CP [6, 11, 22, 25-28].

Previously published studies demonstrated an increase in ankle ROM after BoNT-A injections and normalization of ankle dorsiflexion at mid-stance of the gait cycle. Injections into hamstring group resulted in improved knee extension angle throughout the stance phase [6, 18, 29, 30].

According to the European consensus on the use of BoNT-A, the percentage of patients with spastic CP who can benefit from this treatment varies from 50 to 75% depending on the age and GMFCS level [22].

Nevertheless, only an appropriate approach to Botulinum Toxin therapy can provide required results. In most cases, complex treatment should associate Botulinum Toxin therapy to facilitate the use of orthotics, kinesiotherapy and physical methods of rehabilitation [23, 30]. Botulinum toxin is not intended to serve as replacement of physical therapy but should be considered as add-on to the modern therapeutic strategies instead. Indeed, an advanced use of physical therapy and optimal splinting following Botulinum Toxin therapy is substantiated for increasing the effect of muscle relaxation which facilitates muscle stretch exercises. An intensive physical therapy delays a subsequent injection of botulinum toxin, which favors the muscular growth and, therefore, improves long-term outcomes [11, 29]. By combining botulinum toxin administration with rehabilitation measures, an improvement can be achieved even in severe CP cases associated with pronounced spastic disorders [29, 31].

According to the modern concept, Botulinum Toxin therapy should be done as single-event multilevel intramuscular injections aimed to correct pathologic motor stereotypes and to stimulate motor development of a child with CP [6].

Numerous clinical series demonstrated beneficial effects of botulinum toxin type A on painful muscular spasms, use of bracing devices and prevention of fixed muscular contractures. There are data suggesting that the treatment of the lower limb spasticity with

botulinum toxin type A decreases the energy requirements when moving and increases exercise tolerance in walking children with spastic cerebral palsy [3, 6, 30, 32]. All this leads to improvements in physical health parameters, especially, in the case of early treatment (before the age of 6 years) [18, 29].

Surgery is indicated in case of secondary orthopedic complications in CP [5, 10, 33]. A SEMLS is defined as a surgical intervention on the tendomuscular system and/or bones of two and more anatomical regions performed in a single session during one hospitalization followed by a single rehabilitation period [17]. Despite the consensus achieved in relation to single-event multilevel surgeries, there are different points of view as to the optimal age for the surgery: some authors advocate for intervention in young children aged 4 to 6 years [14, 34] while other authors consider the age of 8 to 12 years optimal [5, 13, 27].

In our study, age of patients varied from 5 to 17 years. We suggest the time for surgical intervention to be determined by occurrence of orthopedic complications. On the other hand, our study revealed that operated on at an earlier age develop recurrent orthopedic complications during pubertal growth spurt and require reoperation in 95% of cases. If orthopedic surgery was postponed by appropriate complex rehabilitation program including BoNT-A, the reoperation rate decreases significantly down to 4.6% of cases.

The outcome of multilevel surgery largely depends on early start of rehabilitation. Our findings showed that low doses of BoNT-A in postoperative short-term allow to control pain syndrome and maintain motivation of children to develop specific motor skills and functions. Our results conform with previously published studies [16, 17, 19, 32]. Botulinum toxin type A provides antinociceptive effect improving quality of life of patients and increase his/her motivation to moving [29, 31].

CONCLUSION

Our studies demonstrated that BoNT-A injections resulted in reduced rate of orthopedic complications requiring surgery in early age, postponed the surgeries in majority of patients and reduced orthopedic issues recurrence after SEMLS. We found a favorable effect of low doses of BoNT-A for postoperative rehabilitation. It should be highlighted that Botulinum Toxin therapy is a part of complex management of CP ensuring effectiveness of postural management, orthotics and kinesiotherapy.

ABSTRACT

Nutritional status malformations are frequently associated with neurological and orthopedic disorders of patients with cerebral palsy (CP). At that, both weight and height excess and deficit can be observed, however, the deficiency of weight and height factors is more clinically significant, that most CP patients demonstrate. According to the recent epidemiological studies, up to 70% of children with cerebral palsy are malnourished [1, 2, 3]. Nutritional disorders in children with cerebral palsy were also reported by Studenikin V.M. and Buksh A.A. (2016), Aydin K. et al. (2018), Scarpato E. et al. (2017), García Íñiguez J.A. et al. (2018) [4, 5, 6]. Nutritional disorders in children with CP include weight loss of varying degrees, growth disturbance, micronutrient inefficiency, osteopenia, and obesity [7]. Nutritional disorders in children with cerebral palsy are associated with growth inhibition, subpar growth curve, impaired peripheral circulation, immune system failure, impaired wound healing, breathing muscles weakness, and an increased risk of pathologic fractures [8, 9]. The functional effect of such concomitant disorders can be so strong that its negative impact on everyday activity and participation can be much more significant than from motor problems caused by CP, and depending on the disease severity. Typically, nutritional status disorders occur in children with severe motor impairment (GMFCS levels III-V) and cognitive deficiency [10]. This category of children demonstrates significant orthopedic complications, which often require a multi-stage surgical correction causing a long hospital stay of the child.

1. WEIGHT DEFICIT AND MALNOURISHMENT IN CEREBRAL PALSY

The nutritional deficiency in children with CP increases the risk of developing intercurrent diseases (cardiovascular, endocrine, immune systems, respiratory failure) [11, 12, 13, 14, 9, 15], impaired tissue tropism (pressure sores nascency, impaired wound healing, muscle atrophy, decreased bone mineralization) [16, 17, 18], the decrease in the efficiency of specialized medical care [19], the development of side effects from a specific (anticonvulsant, hormonal, etc.) therapy [20]. As a result, children with cerebral palsy have a relatively high frequency and duration of hospital stays and the related increase of 20-30% in the costs of managing each patient [21, 22].

Malnutrition in CP is the result of the following causes and factors: 1) feeding difficulties as a result of chewing and swallowing disorders (the incoordination of lips, tongue, palate, and pharynx muscle movements); 2) a slow development caused by the damage of the brain centers that provide nutrition and growth (hypothalamic centers); 3) tooth decay/enamel hypoplasia and other dental problems; 4) the discrepancy of food habits to individual energy needs; 5) mineral deficiency caused by a chronic use of anticonvulsants or lack of active movements; 6) underlying diseases of the gastro-intestinal tract [23].

Oral-motor disorders are one of the main factors that determine difficulties during eating and drinking in patients with CP. The uncoordinated work of tongue and pharynx muscles, disruptions in the jaw functioning lead to slow chewing, difficulties with swallowing, the need to eat a certain food consistency, a high risk of aspiration during eating and drinking, which leads to a decrease in the amount of food consumed and, as a result, malnutrition. According to the study by S. Reilly et al. [24], every third child with oral-motor problems had a restriction on the texture and consistency of food and liquid taken. 60% of children were completely dependent on their parents during feeding and could not eat on their own, 57 % of children choked on food and had episodes of aspiration in infancy. The authors of the study found a connection between the severity of dysphagia and motor disorders: a severe oral motor dysfunction was reported in children with more significant motor disorders. Further studies also confirm a direct correlation between the severity of motor disorders and the severity of dysphagia [25, 26, 27].

Dental problems such as ulcers, oral candidacies, tooth decay, gingivitis caused by a poor oral hygiene worsen eating disorders [8] and, according to Jan B.M. and Jan M.M. (2016), may have a harmful effect on health and a negative impact on the quality of life [28]. Cardoso A. M. R. et al. (2018) conducted a study of 149 CP patients (age 2-18) who were assessed by the factors affecting the quality of life related to health (Health-Related Quality of Life - HRQoL) and the quality of life related to oral health (Oral Health-Related Quality of Life – OHRQoL) [29]. Consequently, it proved that patients with cerebral palsy had lower HRQoL and OHRQoL indices than healthy peers. It was shown that the average OHRQoL index of 78.0 ± 24.6 in the study group was 12.1% associated with the age, presence of gastroesophageal reflux disease, tooth decay, and periodontics [16]. Rodriguez J. P. L. et al. (2018) examined 120 children and adolescents with various CP forms (spastic - 62.5%, mixed - 18.3%, atactic - 10%, athetoid - 9.1%) [7]. Tooth decay was most frequently detected in children with a mixed form of cerebral palsy compared to other patients ($p < 0.05$). Among other types of dental pathologies, the researchers identified erosion and traumatic injuries of

the teeth, pathological occlusion (dental bite), regular oral muscle actions, Gum Hyperplasia, and dental fluorosis. The detection rate of pathological occlusion was 87.5% [7].

Children with CP often find it difficult to maintain oral hygiene at an acceptable level due to a variety of factors. In particular, children with nasal breathing problems and hypersalivation are particularly prone to have difficulties with maintaining oral hygiene [8]. The presence of GERD can also increase the risk of tooth decay as constant acid reflux destroys the tooth enamel [30]. Motor disorders can contribute to difficulties in maintaining a proper oral hygiene. For example, Sedky N.A. (2018) evaluated the teeth and oral cavity health in 62 patients with cerebral palsy aged 3-12, correlating them with the type of disease and the GMFCS scale [31]. 84% of the examined children had spastic tetraparesis, 41.9% of them were sitting with support, 32.3% of the patients matched GMFCS level IV, and 29% matched GMFCS level V. Tooth decay was detected in 54.8% of the cases, and 43.6% of the patients had severe gum inflammation. Children, who used a support while sitting, did not hold their head, and stood with a support were more likely to have tooth decay than those who had the skill of sitting and walking independently. Accordingly, tooth decay was indicated more frequently in patients with GMFCS levels IV/V. In older children, significant gingivitis was more often detected [31].

Among the gastroenterological problems that often lead to nutritional disorders in children with cerebral palsy, the list should include as follows: decreased appetite, dysphagia (oral, pharyngeal, esophageal), nutritional dysfunction, hypersalivation, chronic constipation, gastroesophageal reflux disease, etc. [32]. GERD is one of the concomitant conditions occurring frequently in children with cerebral palsy and complicating significantly their feeding [30]. Risk factors for GERD in children with CP and severe motor function restriction are the disruption of the gastrointestinal tract smooth muscle cells innervation, which leads to a decrease in the lower esophageal sphincter tonus, gastric emptying rate, esophagus dysmotility; general spasticity; inability to sustain a pose, short duration of verticalization; convulsive disorder; taking antiepilepsy drugs; postural disorder, etc. [33]. Aspiration pneumonia and refusal to eat, which often occur in GERD, can be a serious obstacle to an efficient nutritional support for children with CP and are prognostically unfavorable signs [34].

Constipation is a serious comorbid condition in children with cerebral palsy. Campanozzi A. et al. (2007) described a high prevalence rate of constipation in children with severe cerebral palsy in more than 50% of the cases [35], which may be associated with difficulties in the inguinal and perineal zone care in patients with hip joints adduction contracture and a high risk of the urinary tract and skin infection development.

2. MICRONUTRIENT STATUS IN CHILDREN WITH CEREBRAL PALSY

Micronutrients, which barely provide food energy intake, perform many important roles that are of particular importance in CP.

Bone fractures associated with diminished bone mineralization pose a major problem in children with spastic tetraparesis. Some children with CP take anticonvulsants (to control epileptic seizures); their use is associated with Calcium and vitamin D metabolism imbalance. Some antiepileptic drugs stimulate the hepatic microsomal enzyme system, increasing the 25-

hydroxyvitamin D conversion to active metabolites, thereby reducing the availability of vitamin D for the body. This increases the risk of bone fractures in the given group of children. Folic acid deficiency has also been reported among people taking antiepileptic drugs [32]. Hillesund E. et al. (2007), when examining the group of children with CP, determined that these patients had a deficiency in a range of micronutrients (minerals and vitamins): iron, calcium, folic acid, niacin, vitamin E and vitamin D. Significantly, the lack of these micronutrients occurred in children even when using special nutritional supplements [16]. According to King W. et al. (2003), in children with spastic tetraparesis, there is often a decrease in bone mass due to insufficient intake of calcium and vitamin D, as well as the use of anticonvulsants (as a result, patients experience a greater risk of non-traumatic bone fractures) [36]. When examining the patients with this form of cerebral palsy, American researchers found a significant decrease in the mineral density of vertebral spine bones compared to healthy individuals, and in 58% of the cases, z-number was less than -2. The history of limb fractures was observed in 39% of the patients; in these cases, z-number values for the density of vertebral spine bones were significantly lower than in patients without any indications of previous fractures [36]. Papadopoulos A. et al. (2008) note a high degree of incidence of iron-deficient anemia among patients with CP, which, in their opinion, is a direct consequence of insufficient consumption of nutritional iron [37]. Hypochromic anemia was detected in 33% of the patients, and in 38% of the children due to iron deficiency. There were no statistical differences in the iron deficiency degree of incidence depending on age; the tests aimed at detecting occult blood and/or intestinal parasites in the fecal matter were negative; the levels of folic acid and vitamin B12 in blood corresponded to the age norm. The researchers established that anemia and iron deficiency were observed in 95.6% of the patients who received liquid nutrition, and among the children who received a regular diet, anemia and iron deficiency were much less common – 18.8% and 22.3% of the patients, respectively. The authors conclude that a high degree of anemia incidence in patients with CP is the result of inadequate intake of iron with food and its delayed absorption, which suggests the need for appropriate supplementation [37]. In their review, Schoendorfer N. et al. (2010) address publications on the availability of vitamins and minerals for children with cerebral palsy and the impact of various micronutrient deficiencies on various aspects of their health [38]. The authors emphasize that it is common for children with cerebral palsy to have difficulties with eating that impact negatively on their development indicators, overall health and life expectancy. In their opinion, unreasonably few studies and publications are related to the micronutrient status in cerebral palsy, while the main part of the scientific search is aimed primarily at the problem of energy consumption in this group of patients. Meanwhile, a recognized role of micronutrients in maintaining cellular homeostasis of the entire body determines the necessity to focus attention and efforts of researchers on this specific area [38].

3. NUTRITIONAL STATUS ASSESSMENT IN CP CHILDREN

The nutritional status assessment in children with CP is a difficult task for clinicians. Features of physical development, metabolism, and numerous neurological disorders in children with CP determine the need to use several non-invasive techniques for an objective

nutrition assessment (Table 1). However, it should be noted that only a comprehensive multidisciplinary approach to the CP child rehabilitation, when the nutritional status assessment and nutritional correction are significant, will increase the efficiency of rehabilitation measures, reduce the number of complications and improve the life quality of patients with CP. The algorithm of nutritional status assessment includes several stages. The first stage involves a physical examination of the patient, study of the dietary history; the second stage is assessing the gross body composition using modern non-invasive methods: anthropometry, bioimpedansometry, osteodensimetry; the third stage is based on the study of energy production using direct and indirect calorimetry; the fourth stage includes the study of biochemical markers of nutritional status. A comprehensive assessment is both necessary to identify problems in development and nutrition, and it allows choosing the right treatment or intervention tactics.

A thorough physical examination can help to determine a deficiency of calories and nutrients. Subcutaneous edema indicates protein malnutrition and may be a sign of heart failure. Paleness or heart murmurs are often present in iron-deficient, folic-deficient, and B12-deficient anemia. Due to chronic aspiration, broncho-obstructive syndrome may occur. The skin, nails and tunica mucosa of the mouth also need to be examined for pathological changes associated with hypovitaminosis D. Wounds can heal poorly if the food does not contain enough calories, vitamins C, E, and zinc [39]. Rachitic rosary, thickening of wrist bones and bowleg, found in the musculoskeletal examination, are signs of vitamin D deficiency. An ophthalmological examination also helps to identify vitamin A deficiency (corneal clouding, conjunctival xerosis) and B1 deficiency (nystagmus, ophthalmoplegia).

Table 1. Evaluation of clinical symptoms related to nutritional disorders

Signs	Possible reasons related to nutrition
Hair	
Dull, dry; no natural gloss; uncombable hair syndrome in the morning	Protein deficiency
Thin, sparse; without curls	Zinc deficiency
Eyes	
Pale, injected sclera	Iron deficiency
Dry sclera; triangular grey spots on the sclera	Vitamin A deficiency
Hyperemia of the eyelids	Riboflavin deficiency
Lips	
Redness and puffiness of the lips; angular stomatitis	Niacin, riboflavin and/or pyridoxine deficiency
Gums	
Spongy, swollen, bleeding	Vitamin C deficiency
Teeth	
Enamel erosion	GER
Face	
Round, edematous	Protein malnutrition, thiamine deficiency
Peeling skin around the nostrils	Vitamin A, zinc, and essential aliphatic acids deficiency

The assessment of the physical development of a child with cerebral palsy involves certain difficulties because such patients have multiple skeletal bone deformities, joint

contractures, involuntary muscle spasm, cognitive and behavioral disorders, therefore, it is impossible to interpret obtained data on the physical development of children with CP according to the generally accepted scores. In 2011 Brooks J. et al. developed the Life Expectancy Project scores that take into account not only physical development, gender and age of the child, but also the level of restriction of global motor skills [40]. The evaluation of physical development indicators on the Life Expectancy Project scores is of great importance in clinical practice, as it also allows assessing the risks of mortality. It is known that in children with GMFCS levels III – V and body weight <20 percentile, the risk of death is 1.5 times higher than in children with normal rates of physical development [41].

To assess the risks of nutritional status malformations, methods for body composition assessment are used along with anthropometric methods [34]. The concept of “body composition” provides an assessment of the water, fat and non-fat solids content (bone and muscle tissue) - lean body mass. The body composition is affected by the ratio of the amount of fat and muscle tissue, changes in the volume of total, extracellular and intracellular fluids [4, 42]. Various methods are used to assess the body composition (caliperometry, bioelectric bioimpedance analysis, X-ray absorptiometry, etc.). Caliperometry helps to assess the state of the fat depot in the body. The thickness of subcutaneous-fat folds indicates the value of the total fat depot in the body and can be measured with a caliper, providing standard pressure on the folds (10 g/mm²). The most common practice is to measure the thickness of the skin fold in the triceps and biceps muscles of the arm, in the infrascapular region, above the crest of the iliac crest, along the anterior axillary line. Yakut A. et al. (2006) demonstrated that the thickness of the skin fold above the triceps is an optimum indicator for nutritional status assessment in CP [43]. The bioimpedance analysis of the body composition allows assessing the status of protein, fat, and water metabolism, the intensity of metabolic processes, and assessing the body's reserve capacity and disease risks based on the electrical resistance (impedance) of the human body and anthropometric data. According to ESPGHNG recommendations, this method of functional diagnostics enables us to determine absolute and relative values of the body composition individual components and metabolic correlates and to assess objectively the patient's nutritional status [34]. The research conducted by Oeffinger D.J. et al. [44] proves a high assessment accuracy of the body composition components using bioimpedansometry and estimating the skin fold thickness using Gurka equations in CP children with mild motor disorders.

Dual energy X-ray absorptiometry is the most common and preferred method for bone status assessment [45]. Dual energy X-ray absorptiometry works on a three-component model (muscle, fat, and bone). The method is based on measuring the attenuation of the X-ray flux when passing through bone, fat, and muscle tissues of the body. The exposure to radiation is extremely low in comparison with fluoroscopy and computerized tomography. As a rule, in children with CP, the distal segment of the femoral bone is chosen for BMD scanning because this area is most likely to fracture, and it is easily accessible. Current guidelines, based on the expert opinion, recommend prescribing dual energy X-ray absorptiometry only in case of a pathologic fracture. Performing the procedure at the treatment beginning and after the intervention helps to analyze changes in the BMD. The results of the bone density study should be compared to reference standards and presented as Z-scores, adjusted to the child's age, gender, and height [46]. Using the most advanced X-ray densitometers and installed “Total Body” software, it is possible to accurately determine both the bone strength and total body fat percentage, and to assess the content of soft lean mass and fatty tissue in various

body segments. Given the minimum error of the measurement (no more than 1-3%), this method can be used as the “gold standard” for accessing the body composition components.

Determining the intake of actual calories and micronutrients in relation to the body’s desirable physiological need for them is an integral part of the nutritional status assessment. For example, knowing whether a child intakes enough calories can reveal the etiology of malnutrition. There are several different ways to evaluate the required child’s energy intake. The most accurate method is indirect calorimetry, which allows the patient to determine the number of calories, proteins, fats and carbohydrates needed based on the expired air analysis. Indirect calorimetry is performed with a fase mask metabolimeter or a mask for patients with spontaneous breathing. The study is carried out at rest with passive and active loads. Currently, various equations are available to assess energy consumption in children with CP. In 2011, Rieken et al. proposed a method for estimating the basal metabolism rate using well-known Schofield equation [47]. The Schofield-based method became widely used in determining energy needs in children with CP because of its simplicity. The Rieken daily energy need calculation method is used to determine the basic energy requirements, which are then used to calculate the total energy consumption, corrected for physical activity levels, GMFCS level, and the overall energy consumption correction based on the cerebral palsy presence. The Rieken daily energy need calculation formulas using the Schofield equation are shown in Table 2.

Table 2. Calculating daily energy need in children with cerebral palsy [47]

	Schofield Equation Method
3-9 years old	
Boys	$BMR = (0.095 \times \text{weight, kg}) + 2.110$
Girls	$BMR = (0.085 \times \text{weight, kg}) + 2.033$
10-18 years old	
Boys	$BMR = (0.074 \times \text{weight, kg}) + 2.754$
Girls	$BMR = (0.056 \times \text{weight, kg}) + 2.898$
Total energy consumption, kcal	$1.1 \times BMR \times 238.8$
Additional correction:	
General correction	- 280 kcal
physical activity energy costs	+ 222 kcal
GMFCS level IV	+ 431 kcal

Note: BMR - basic metabolism rate, kJ; TBW - total body water; DLV-double labeled water.

Laboratory tests can be extremely useful in assessing the nutritional status of a CP patient. Mostly, preliminary studies include a general blood test, counting absolute lymphocytes, biochemical analysis and determining the indicators of protein metabolism, lipid pattern, hepatic and renal function indicators, serum iron, and 25 (OH) D - major metabolite of vitamin D. Further blood tests for folic acid and vitamin B12 levels may be prescribed, depending on the presence and type of anemia. Regular testing of 25-OH vitamin D level and, if possible, alkaline phosphatase, calcium and phosphorus are advised for children with CP, and the motor activity should be restricted for those who take anticonvulsants [19]. Low levels of prealbumin, retinol-binding protein, and transferrin may indicate a protein deficiency, although, due to a longer half-life, albumin is still the best indicator of chronic malnutrition. Depending on the physical examination results and

anamnesis, additional laboratory tests are necessary to exclude other causes of physical development delay, including hypothyroidism or hyperthyroidism (free thyroxine, thyroid-stimulating hormone), growth hormone hunger (IGF-1, STH-stimulating tests with glucagon), delayed puberty (follicle-stimulating hormone, luteinizing hormone, estradiol, testosterone), inflammatory diseases (C-reactive protein, ferritin), celiac syndrome (IgA to tTG and deamidated gliadin peptides, total IgA level), and chronic infections of the urinary organs (common urine test, urine culture test). To interpret the skill of taking solid and liquid food in children with CP, Seiers D., Anne Mandi et al. (2014) validated the Eating Drinking Assessment Classification System (EDACS). The scale can be used to assort the ability of taking food and liquids in terms of efficiency and safety, and to determine the amount of help needed for levels I - V in this scale. Starting from level II, a physician must evaluate the associated clinical pattern: 1) frequent (possibly of aspirating nature) bronchitis and pneumonia; 2) negative weight changes; 3) the capability of a child to consume a sufficient amount of food; 4) the duration of existing changes (during an acute condition, for several months). Videofluoroscopy is a necessary tool to determine the degree of meal safety. This study remains the “gold standard” for diagnosing dysphagia and selecting the food bolus consistency. The method includes a dynamic fluoroscopic assessment of oral, oral-transfer, pharyngeal, and partially esophageal stages of swallowing. It allows detecting aspiration before, during, and after swallowing, determining dysphagia location, and its possible cause (a muscle spasm of the esophagus). It can also help to choose the best feeding position, appropriate consistency, and feeding speed [8].

4. NUTRITIONAL SUPPORT IN THE PERIOPERATIVE PERIOD

Nutritional status normalization is an important component of the preoperative preparation in patients with CP as the incidence rate of postoperative complications increases with malnutrition, which affects the course and duration of the postoperative period, and the efficiency of treatment in general. Thus, Baranek E.S. et al. (2019) published the results of the study demonstrating a high correlation between the preoperative BMI percentile in stratified GMFCS growth charts and SSI (Surgical Site Infection) after spinal surgery [48].

The general principles of approaches to the nutritional status correction in patients with CP are as follows:

- involvement of specialized professionals: gastroenterologist, dietitian-nutritionist;
- correction of comorbidity affecting food consumption and digestion processes;
- calculation of the daily caloric value taking into account the basic metabolism, cerebral palsy form, severity of motor disorders, perioperative energy consumption compensation;
- selection of the food type (natural nutrition or specialized supplements), the consistency of food, diet, ways of nutrients intake.

A surgical intervention, like any other injurious exposure on the body, causes a number of reactions, including the catecholamine and pro-inflammatory cytokine discharge, which inevitably contributes to the development of hypermetabolism and catabolism with excessive

surgical release of energy substances [39, 49]. In the setting of already existing nutritional inefficiency, hypermetabolism, as a result of surgical stress, leads to a further decrease of growth process, an increase in cognitive deficiency, an increased risk of infectious complications, a delayed soft tissue regeneration and bone union. The occurrence of these disorders results in a delayed commencement of postoperative rehabilitation and its increased duration, which ultimately reduces the efficiency of treatment and rehabilitation measures. ERAS (enhanced recovery after surgery) rehabilitation programs include preoperative preparation and drug therapy, fluid balance, anesthesia and postoperative analgesia regimens, perioperative nutrition, and surgical release. The ERAS concept is aimed at reducing the time of treatment and recovery after surgery and involves, along with the widespread use of field block anesthesia and minimizing the use of opioids, the earliest possible recovery of vital functions, and, if possible, patient's motor activity. The perioperative nutritional support in this approach is considered an integral part of early activation of a patient.

In addition to a faster recovery through accelerated rehabilitation programs after surgery, more and more publications indicate that these programs reduce the risks of postoperative complications.

The ERAS concept involves reducing the time of preoperative fasting and anhydrous periods and starting postoperative nutrition as early as possible as a way of reducing postoperative hypermetabolism and catabolism. In the preoperative period, despite the tendency of reducing the duration of preoperative fasting, it remains mandatory for patients with CP to refuse food no later than 6 hours before anesthesia. This measure is associated with the gastro-intestinal tract dysmotility, especially in the upper parts, in children with cerebral palsy. The consequences of forced fasting in patients with malnourishment are obvious: oligemia, further glycogen depletion in the muscles, hypoglycemia, and metabolic stress. However, preoperative fasting is associated with significant metabolic shifts and negatively affects the course of the postoperative period. To reduce the preoperative fasting period, it is possible to prescribe special nutritional care medicine – high-caloric carbohydrate maltodextrin-based drinks with hydrolyzed vegetable protein and additional ingredients. These medications do not contain any fat and dietary fiber, and this induces fast gastric emptying in less than two hours. Taking carbohydrate drinks two hours before surgery reduces metabolic stress and improves perioperative metabolism, reduces hunger and thirst, and makes the preoperative period more comfortable for the patient [50]. These medications can be used in the preoperative period in children from 1 year old.

Due to frequent problems with food consumption and digestion, which are initially present in patients with CP, as well as a higher rate of postoperative nausea and vomiting, and a decrease in appetite in the early postoperative period, it is extremely difficult to achieve a proper nutritional support with only natural nutrition in the next few days after surgery. Current ESPEN guidelines (European Society for Clinical Nutrition and Metabolism) give priority to enteral nutrition in patients who cannot meet at least 50% of their energy needs orally for more than 7 days. For these purposes, nutritional care medications are designed, they allow both providing CP patients with all the necessary energy and flexible substances, and solving a number of specific problems with feeding these patients. In addition to macro- and micronutrients, nutritional care medications usually contain additives that improve food digestion and gastro-intestinal tract motility, such as dietary fibers, probiotics, and certain pharmaconutrients designed to reduce the inflammatory reaction and oxidative stress. It is possible to use standard isocaloric mixtures during the postoperative period in patients with

CP without severe dysphagia and nutritional status malformations. Usually, such patients can also eat traditional food, and nutritional care can be prescribed additionally.

Patients with nutritional deficiency, dysphagia, difficulties in digesting large amounts of food, but capable of oral alimentation, use medications with increased energy density (1.5–2 kcal/ml) and high protein content (5–10 g/100 ml), which reduces the amount of nutrition. The ratio of macro- and micronutrients in such medications meets the specific needs of children. These medications meet all the nutritional requirements for children with malformed nutritional status; they use medium chain fat as sources of fat – the most easily digestible type of fat that is digested independently from pancreatic lipase. To correct the immune status and metabolism of postoperative patients, it is possible to use nutritional care medications containing omega-3 aliphatic acid, L-carnitine and individual amino acids (arginine, glutamine). For patients with dysphagia, special medications with higher viscosity of different consistency have been developed. It is also possible to create an optimum consistency of nutrition for swallowing by adding thickeners to any liquid, including nutrition therapy medications.

Patients with gastro-intestinal tract dysmotility and GERD are prescribed anti-reflux mixtures based on partially or completely hydrolyzed milk whey protein. Thanks to the hydrolyzed milk protein, the medicine is quickly excreted from the stomach, and it fully absorbs, even in cases of severe digestive disorders and intestinal absorption. These products can be either standard or high-protein. It is possible to use them both for oral and enteral feeding in children older than 1 year. For patients suffering from constipation, dietary fiber mixtures are prescribed to improve gastro-intestinal tract motility.

If oral feeding is not possible or difficult in the postoperative period, tube feeding is used in patients with CP. Modern probe enteral nutrition is carried out by using enteromats with a controlled speed, which reduces the risk of regurgitation and contributes to a better food absorption. Depending on the degree of nutritional disorders, both standard and hypercaloric high protein mixtures can be used for enteral nutrition. Mixtures for enteral nutrition fully cover the daily need for macro- and micronutrients, and they can be used for GERD and malabsorption syndrome. These mixtures can be used for PEG feeding.

CONCLUSION

Nutrition disorders in children with CP are a largely underestimated problem, including the preparation process for surgical treatment. Numerous research data indicate that malnutrition affects health and life quality of patients with CP, and worsens the prognosis for the underlying disease. Meanwhile, different degrees of motor disorders cause difficulties in standardizing approaches to determine the nutritional status and correct it in such patients. The severity of nutritional disorders usually increases with a decrease in the ability of patients to move independently, and it correlates with a decrease in intellectual abilities. The assessment, correction and support of nutritional status should be an integral part of management and rehabilitation measures and of the perioperative period as they generally influence the efficiency of treatment.

ABSTRACT

Introduction. Single-event multilevel surgery is the gold standard of care to treat gait problems in children with cerebral palsy. SEMLS is not a uniform procedure but is tailored to the patient's needs and includes realigning bony levers, lengthening or transferring muscle-tendon units. A key element for planning surgical treatment is comprehensive assessment of gait disorders.

The *purpose* of this study was to evaluate the results of surgical orthopedic management in patients with true equinus gait and jump gait using Gillette Functional Assessment Questionnaire, Edinburgh gait score and three-dimensional gait analysis in a sample of subjects with cerebral palsy.

Material and methods. This study was a retrospective review of all patients (56 children, mean age 8.8 ± 2.6 years) diagnosed with CP having true equinus or jump knee gait who were treated with SEMLS at a single institution. The other inclusion criteria used for patient selection were medical history for more 1.5 year of follow-up; spastic diplegia and tetraplegia corresponding to level I or II GMFCS.

The Edinburgh score and three-dimensional gait analysis were performed before surgery and at a minimum of 1.5 years after surgery. The subjects were also scored using the Gillette Functional Assessment Questionnaire.

Results. The Edinburgh visual gait score revealed significant improvement in the kinematic parameters at latest follow-up examination. The mean total score was reduced

* Corresponding Author's Email: leon4yk@mail.ru.

from 42.7 to 15.3. This strongest of the rank correlation coefficient between total Edinburgh score and FAQ was at $r = -0.825$ (before surgery) and $r = -0.845$ (2-3 years follow-up control). The correlation was negative for the both period of clinical examination. It was preoperatively revealed that the maximum deviations in the parameters “knee progression angle” and “trunk maximal lateral shift” of the Edinburgh scale correlates with clinically significant torsional femoral deformities requiring surgical correction.

In long-term, three-dimensional gait analysis revealed improved ankle joints kinematics and normal values of foot progression angle. Knee joint flexion decreased significantly during the stance phase. We observed decrease in the magnitude of maximum swing-phase knee flexion. The hip decreased its flexion at initial contact, peak hip extension achieved physiological values. Kinetic data showed that timing of maximum at ankle moment had improved significantly as well as generated ankle power representing the increased push-off ability of the foot during walking. The knee joint reduced its moment.

Conclusion. Multilevel orthopedic surgery in CP children with true equinus and jump knee gait significantly improve kinematic and kinetic parameters of gait cycle, both directly related to muscular contractions, foot deformities and rotational abnormalities and due to incorrect compensating biomechanical position of the distant segments. Rotational abnormalities should be revealed and quantified considering kinematic data. Correction of rotational abnormalities and surgical improvement of gait disorders in the sagittal plane should be performed simultaneously. Intramuscular aponeurotic recession associated with other elements of multi-level surgical event does not impair maximum power generation at the ankle representing the increased push-off ability.

Keywords: cerebral palsy, true equinus gait, jump gait, torsion deformities, orthopedic surgical treatment, gait analysis

INTRODUCTION

Cerebral palsy (CP) is the most common motor disorder in children with an incidence from two to five cases per 1,000 newborns [1–4]. In Russia, the reported incidence of cerebral palsy varies from 2.2 to 3.8 per 1,000 births. Spastic cerebral palsy types represent over 80 % of CP population [5, 6].

Despite the CP is a stable encephalopathy, progressive orthopedic secondary complications are the principle cause of motor activity impairment in CP children [7-9]. The etiology of true equinus gait and jump knee gait is multi-factorial. The factors include abnormal motor control, spasticity, muscle weakness and imbalance, torsional deformities resulting in progressive muscle contractures, foot deformities and lever arm disfunction. These two patterns are characterized by similar parameters; thus, the cases with those gait abnormalities may be united for analysis of treatment outcomes [10, 11].

Single-event multilevel surgery (SEMLS) is the actual standard of care to treat gait problems in children with cerebral palsy. SEMLS is not a uniform procedure but is tailored to the patient's needs and includes realigning bony levers, lengthening or transferring muscle-tendon units [12-15]. A key element for planning surgical treatment is comprehensive assessment of gait disorders. Based on computer gait analysis, the main pathological patterns in spastic diplegia have been identified [16-20]. Lofterød et al. [21] and Simon et al. [22] emphasize the role of the three-dimensional gait analysis both for understanding the

pathology of motions and planning surgical events, for control of gait development and its modifications in the long-term follow-up. If three-dimensional gait analysis is unavailable, observation scales based on goniometric data on video recordings in orthogonal planes are recommended [23-25]. Novacheck [24] and Read [26] showed that the Edinburgh visual gait score, developed specifically for the gait analysis of patients with CP, correlates with the Gillette Gait Index and the Gillette Functional Assessment Questionnaire (FAQ).

The purpose of this study was to evaluate the results of surgical orthopedic management in patients with true equinus gait and jump gait using FAQ, Edinburgh gait score and three-dimensional gait analysis in a sample of subjects with cerebral palsy.

MATERIAL AND METHODS

This study was a retrospective review of all patients diagnosed with CP having true equinus or jump knee gait who were treated with SEMLS at a single institution. The other inclusion criteria used for patient selection were medical history for more 1.5 year of follow-up; spastic diplegia and tetraplegia corresponding to level I or II GMFCS.

Gait analysis using the Edinburgh score was performed before surgery and at a minimum of 1.5 years after surgery. The subjects were also scored using the Gillette Functional Assessment Questionnaire (FAQ) [27] before first surgery and in 1,5-2 years after single event multilevel orthopedic surgery.

Three-dimensional gait analysis was also carried out on all subjects walking barefoot. Kinematic and kinetic variables were evaluated before surgery and at last follow-up. We used 6-camerax Qualisys Oqus system and one AMTI force plate (Advanced Mechanical Technology Inc., Watertown, MA) to collect motion analysis data. In the Ilizarov Gait Analysis Laboratory the IOR model was used for markers [28], which is optimal for minimal system configuration and for appropriate kinematic analysis to decrease artefacts of skin motion. The Delphi consensus was applied to classify observed pathologic gait patterns [29]. Preoperative values were compared with those at the last follow-up.

AtteStat 12.0.5 software was used for the statistical analyses. The statistical values described the mean and standard deviation. The Edinburgh score data were compared by using Wilcoxon signed-ranks test for matched pairs. The test was two-tailed with a 0.05 level of significance. Spearman's rank correlation score was used to assess correlation between Edinburgh score and FAQ. The chi-square test determined the significance of differences in the Edinburgh scale in patients with or without clinically significant torsion femoral deformities. The specificity and sensitivity of associated Edinburgh score maximum deviations of the "knee progression angle" and "trunk maximal lateral shift" were determined as criterium justifying surgical intervention.

This research was approved by the Ilizarov Center Review Board. The study complies with the Declaration of Helsinki statement on medical protocol and ethics. Representatives of all patients enrolled in the study provided oral and written informed consent.

RESULTS

Initially, 117 charts were reviewed from children with spastic diplegia level I, II GMFCS who underwent SEMLS and clinical gait analysis. There were 56 children with spastic CP meeting our criteria for true equinus and jump knee gait.

Not all measures were available for every subject, resulting in a total of 56 subjects (26 girls and 30 boys) being scored for the Edinburgh score, 56 also being scored for FAQ, and 15 being scored for three-dimensional gait analysis. Mean age at surgery was 8.8 ± 2.6 years. Fourteen patients had level I of GMFCS, 52 patients were of level II GMFCS. One surgical event included an average of 7.7 elements (Table 1).

Furthermore, in 12 patients (24 femurs) torsional femoral deformities were underestimated before initial surgery. At 1-year FU control, revealed rotational abnormalities of the gait were recognized clinically significant. Thus, 12 patients underwent correction of torsion deformities in 12 to 15 months after the initial SEMLS.

The Edinburgh visual gait score revealed significant improvement in the kinematic parameters in 1-year follow-up period. The mean total score was reduced from 42.7 to 15.3. The most significant ameliorations were observed in stance regarding initial contact, heel lift, maximum ankle dorsiflexion, peak knee extension, peak hip extension, trunk maximum lateral shift, foot progression angle, knee progression angle (Figures 1-4; Table 2). The decrease of some swing parameter values was also observed: maximum ankle dorsiflexion, peak knee flexion, clearance, knee terminal swing position. Further amelioration of the gait parameters was progressive and observed at latest follow up control in 2-3 years after surgery.

Table 1. Elements of initial SEMLS

Surgery element	Number
Hamstring lengthening	112
Lengthening of adductors, m. gracilis	44
Strayer or Vulpius procedure	112
Grice procedure	48
Evans procedure	14
Shortening of m. tibialis posterior tendon	86
Detorsion osteotomy of the femur	10
Detorsion osteotomy of the tibia	6
Total	432

Figure 1. Patient B, 6 y.o. girl, II GMFCS, equinus gait, before surgery: Knee and ankle terminal swing position (a), initial contact (b), plantar flexion in middle stance (c), heel lift (d), toe-off (e), clearance (f), knee and ankle terminal swing position (h).

Table 2. Mean values of Edinburgh visual gait score

Parameter	Before surgery	12 months FU	2-3 years FU
Initial contact	2.0	0.83	0.75
Heel lift	1.93	0.7	0.5
Maximum ankle dorsiflexion	1.73	0.3	0.21
Hind-foot varus/valgus	1.2	0.1	0.13
Foot progression angle	1.43	0.77	0.54
Knee progression angle	1.2	0.7	0.46
Peak knee extension	1	0.13	0.13
Peak hip extension	0.8	0.13	0.13
Pelvic obliquity at Mid-Stance	0.93	0.63	0.5
Pelvic rotation at Mid-Stance	0.73	0.5	0.3
Trunk Peak Sagittal Position	1.07	0.6	0.58
Trunk maximum lateral shift	1.53	1.23	0.75
Clearance	0.9	0.27	0.13
Maximum ankle dorsiflexion	1.47	0.4	0.33
Peak knee flexion	1.1	0.37	0.125
Knee terminal swing position	1.46	0.1	0.04
Peak hip flexion	1.2	0.13	0.08
Total	42.7	15.3	11.3

Figure 2. Patient B, before surgery: internal knee and ankle progression angle in middle stance for right leg (a) and left leg (b); radiograph of both femurs, AP view (c); CT scan, femoral neck anteversion 39.8° in right hip, 40.5° in left hip (d).

Figure 3. Patient B, 8.5 y.o. girl, II GMFCS, 2 years after surgery: Knee and ankle terminal swing position (a), initial contact (b), plantar flexion in middle stance (c,d), heel lift (e), clearance (f), knee and ankle terminal swing position (g).

Figure 4. Patient B, 8.5 y.o. girl, II GMFCS, 2 years after surgery: normal knee and ankle progression angle in middle stance for right leg (a) and left leg (b); radiograph of both femurs on the day of bilateral surgery, AP view (c); radiograph of both femurs in 2 years after surgery, AP view (d).

Table 3. Correlation of Edinburgh scores and FAQ

Period	Edinburgh score	FAQ	Spearman
Before surgery	42.7	3.8	-0.825
In 12 months	15.3	6.3	-0.491
In 2-3 years	11.3	7.7	-0.845

Table 3 demonstrates correlation between total Edinburgh score and FAQ. This strongest of the rank correlation coefficient was with the Gillette FAQ at $r = -0.825$ (before surgery) and $r = -0.845$ (2-3 years follow-up control). The correlation was negative for the both periods of clinical examination.

Figure 5. Scatterplot of Gillette FAQ against Edinburgh Gait score in 12 months after the initial surgery. Cases with clinically significant torsion deformities are marked with “T”.

Figure 6. Scatterplot of Gillette FAQ against Edinburgh Gait score in 12 months after the initial surgery representing only cases without torsional abnormalities. Negative correlation values become significant.

In 12 patients, pathological kinematic values of foot and knee progression angles related to underestimated torsional deformity allowed to reveal and justified additional surgeries in 12-15 months after initial interventions. Figures 5 and 6 present scatterplots of Gillette FAQ against Edinburgh Gait score for a period of 12 months after the initial operation. If only cases without torsional deformities have been taken into consideration (Figure 6), the negative correlation becomes significant with stronger Spearman correlation coefficient. The correlation becomes the weakest if all cases are included in the analysis regardless presence or not of torsional abnormalities.

An analysis of correlation between data of Gillette FAQ and Edinburgh visual gait score are presented separately for the both group without torsional deformity and group with clinically significant torsional deformity (Table 4). We believe that the loss of correlation between Gillette score and FAQ in 12 months after surgery for group with uncorrected torsional deformity is due to gait disorders related to torsional abnormalities. The additional surgery for torsional deformity allowed to achieve strong correlation between these measures at latest follow-up control.

Table 4. Spearman's rank correlation score for Edinburgh scale and FAQ represented separately for group without torsional deformities and for group with internal torsion of femur

	Before treatment		12 months FU		2-3 years FU	
	no torsional deformity	Torsional deformity	no torsional deformity	Torsional deformity	no torsional deformity	Torsional deformity
Edinburgh score	42.5	43.2	13.4	23.2	9.75	14.6
FAQ	3.7	4.1	6.5	6.0	7.9	7.2
Spearman	-0.836 (p = 0.9999)	-0.873 (p = 0.9995)	-0.645 (p = 0.9989)	-0.194 (p = 0.7043)	-0.842 (p = 0.999)	-0.776 (p = 0.9958)

Table 5. Correlation of maximal deviations in parameters “knee progression angle” and “trunk maximal lateral shift” of the Edinburgh scale in the initial gait analysis with clinically significant torsion deformities, prognostic significance

	KPA	TMLS	Incidence of association of KPA and TMLS of maximal deviation	chi-square test	Sensitivity	Specificity
No torsional deformity	0.9 ± 0.44	1.25 ± 0.43	7.3%	$p < 0.001$	0.772	0.921
Internal torsional deformity of femur	1.8 ± 0.41	2.0 ± 0.0	84.7%			

It was preoperatively revealed that the maximum deviations in the parameters “knee progression angle” (KPA) and “trunk maximal lateral shift” (TMLS) of the Edinburgh scale correlates with clinically significant torsion deformities. Those rotational gait abnormalities were corrected as part of the first intervention or in 1 year. We should emphasize the high sensitivity and specificity of this finding justifying indication for detorsion osteotomy of femur as an element of SEMLS (Table 5).

The mean values (standard deviation) of kinematic and kinetic parameters revealed by three-dimensional gait analysis are detailed in Tables 6 and 7, in preoperative session and in long term follow-up. The mean value of Gait Profile Score has been improved from $18,1 \pm 3,6$ (preoperative value) to $12,3 \pm 1,9$ (at latest FU control).

In preoperative session, excessive ankle plantarflexion was observed during the whole gait cycle as well as low ankle range of motion. Foot progression was internally orientated. The knee was characterized by excessive flexion during stance and slightly increased and delayed maximum swing-phase knee flexion, which was estimated as compensating. The hip flex-extension graph revealed a increase mean hip flexion angle at initial contact and high flexion during midstance. A limited extension in hip joint in midstance was observed. Pelvic tilt was characterized by normal values while slightly high pelvis excursion was present on transversal plane. Sagittal plane kinetic evaluation showed lack of the first rocker and a unphysiological and early maximum of ankle moment. A lack of power generation at the push-off for the ankle occurred. The knee joint kinematics were characterized by high flexor moment in stance phase of gait cycle.

In long-term FU, ankle joints improved significantly, passing from the previous plantarflexed position to dorsiflexion during stance phase. Three-dimensional gait analysis revealed normal values of foot progression angle. Knee joint flexion decreased significantly during the stance phase, showing the position close to physiological one. We observed decrease in the magnitude of maximum swing-phase knee flexion. The hip decreased its flexion at initial contact, peak hip extension achieved physiological values. After surgery pelvic tilt was in a more physiological position. No changes for pelvis kinematics were displayed in the frontal and transversal planes. Kinetic data showed that timing of maximum at ankle moment had improved significantly as well as generated ankle power representing the increased push-off ability of the foot during walking. The knee joint reduced its moment. No significant changes of knee generated power occurred.

Table 6. Summary of kinematic parameters (mean and standard deviation)

	Preoperative values	2-3 yrs FU
Ankle joint angle at the initial contact (on sagittal plane);	-19,6 ± 10,34	2,1 ± 4,41*
Maximum of ankle dorsiflexion (on sagittal plane) during stance phase;	-14,7 ± 14,83	14,4 ± 5,66*
Range of motion at ankle joint on the sagittal plane during stance phase;	5,6 ± 11,04	17,7 ± 4,58*
Maximum of ankle dorsiflexion (on sagittal plane) during swing phase;	-34,3 ± 15,65	-3,9 ± 7,51*
Foot Progression (foot position on the transversal plane);	-15,1 ± 21,3	6,0 ± 12,7*
Stance Time, %	62,9 ± 6,48	64,1 ± 4,28

Swing peak knee flexion; °	62,3 ± 12,75	56,1 ± 12,75
Timing of peak knee flexion; %	81,1 ± 4,31	77,5 ± 4,65
Gait Profile Score	18,1 ± 3,59	12,3 ± 1,94
Hip joint angle at the initial contact (on sagittal plane);	37,9 ± 8,31	31,3 ± 12,76
Stance peak hip extension;	5,85 ± 9,95	-4,5 ± 12,38*
Stance Hip range of motion; °	40,1 ± 11,66	39,0 ± 9,84
Mean Hip Rotation during all the gait cycle;	16,2 ± 17,3	13,9 ± 9,61
Pelvic Tilt during the gait cycle;	9,4 ± 12,26	9,0 ± 15,36

*Significant difference in comparison to initial mean value ($p < 0.05$).

Table 7. Summary of kinetic parameters (mean and standard deviation)

	Preoperative values	2-3 yrs FU
Timing of maximum of ankle moment; %	23,5 ± 16,4	50,4 ± 3,83*
Maximum value of plantarflexion ankle moment during terminal stance; N*m/Kg	0,70 ± 0,27	0,98 ± 0,24*
Maximum value of generated ankle power during terminal stance; W/Kg	1,17 ± 0,84	1,91 ± 0,85*
Maximum knee flexion moment in stance phase; N*m/Kg	0,37 ± 0,42	0,22 ± 0,19
Knee Power generation; W/kg	0,42 ± 0,30	0,58 ± 0,45
Knee Power relaxation; W/kg	1,24 ± 1,62	1,0 ± 0,60

*Significant difference in comparison to initial mean value ($p < 0.05$).

DISCUSSION

The SEMLS was recognized as gold standard in neuroorthopedic surgery in CP children [12, 13, 15]. The true equinus gait and jump knee gait are most common gait disorders in young CP children. These patterns are caused by spasticity and/or retraction of the plantar flexors of the feet and flexors of the knee joint [19]. If this is associated with critical deterioration of goniometric parameters, surgical orthopedic treatment becomes indicated [30-32]. However, in addition to muscle lengthening procedures, foot deformity and rotational gait abnormality corrections are often included in the program [33-43].

The main surgeon's objectives regarding true equinus gait and jump gait are contractures of the knee and ankle joints of both limbs [25, 44]. On the other hand, it is crucial to avoid unreasonable surgical interventions in diplegia (lengthening of spastic muscles, Achilles tendon lengthening, surgery in young aged under 5 years) [45-47]. Surgery performed in early age leads to the weakness of sural triceps, loss of strength for its eccentric contraction in stance phase. This functional failure results in early excessive knee flexion and progressive knee extensor failure evolving into severe crouch gait and loss of walking ability in the medium-long term [48-50]. The method of choice for triceps lengthening in cerebral palsy is fasciotomy of the calf muscles, which provides an improvement in the kinematic parameters

of the ankle joint without development of crouch gait in the long term [44, 48, 50, 51]. We observed these outcomes in our study: gait parameters and foot kinematics improved in all patients without iatrogenic crouch gait in the long-term follow-up.

According to Gorton et al. [47] and Terjesen et al. [52], the improvement or normalization of ankle joint motion was not associated with compensatory changes in the hip and knee kinematics observed preoperatively. In our study, we noted an improvement in kinematics of the hip and knee joints, estimating this effect as a remote indirect effect of SEMLS. Normalization of knee terminal swing position contributes to appropriate orientation of the foot at the beginning of the stance. That was also reported in the study of Adolfsen [10].

Among other positive effects of multilevel surgery, we found a decrease of compensating flexed position in knee and hip joints in swing phase associated with clearance increase.

It was highlighted that achievement of dorsiflexed position of the foot during stance reduces lever arm disfunction in the sagittal plane [26, 53] and improves the timing of maximum of ankle moment shifting it to the end of stance phase [25, 44, 52]. In our study, simultaneously applied techniques of gastrocnemius fascia lengthening, foot deformity and torsional deformity correction provided increase of ankle power generation during terminal stance in long-term follow up. Dreher et al suggest that gastrocnemius intramuscular aponeurotic recession in cases of spastic diplegic CP sufficiently corrects equinus deformity without risks of overlengthening [54]. Rose et al reported that lengthening of gastrocnemius fascia does not result in weakening of the triceps surae for push-off over the long term [51].

Ounpuu [18] and Theologis [53] pointed out the necessity to simultaneously correct deformities on the transversal plane to eliminate lever arm disfunction and decrease energy consumption during gait. Clinically significant rotational deformities causing every-day functional disabilities require correction in childhood even if there is weak correlation between radiological and gait analysis data of rotational deviation [41]. Our study demonstrated that in CP children with clinically significant rotational abnormalities of the gait, torsional deformity correction is indicated as an element of SEMLS. The association of maximal deviations in knee progression angle and trunk maximum lateral shift of the Edinburgh scale justifies that element of SEMLS. This evaluation criterion has high specificity and sensitivity.

CONCLUSION

This study demonstrated that multilevel orthopedic surgery in CP children with true equinus and jump knee gait significantly improve kinematic and kinetic parameters of gait cycle, both directly related to muscular contractions, foot deformities and rotational abnormalities and due to incorrect compensating biomechanical position of the distant segments. Rotational abnormalities should be revealed and quantified considering kinematic data. Correction of rotational abnormalities and surgical improvement of gait disorders in the sagittal plane should be performed simultaneously. Intramuscular aponeurotic recession associated with other elements of multi-level surgical event does not impair maximum power generation at the ankle representing the increased push-off ability.

ABSTRACT

Stiff knee gait is relatively common specific knee pattern in ambulatory children with cerebral palsy. The *objective* of the study was assessment of results of single-event multilevel orthopedic surgery in patients with cerebral palsy with stiff knee gait.

Material and methods. A total of 20 patients (F/M = 8/12) with a mean age 17.1 ± 12.9 years who presented with stiff knee gait were operated on with single-event multilevel orthopedic surgery (SEMLS). The mean follow-up period was 17 months (range 14-26 months). The distal rectus femoris transfer represented primary treatment in all subjects. Sixteen 16 patients were classified as GMFCS II, 4 patients were GMFCS III. Patients were scored with Edinburgh visual gait score and 3D computed gait analysis (4 patients) before and, at least, 12 months after surgery. Analysis included Gait Profile Score, peak knee flexion in swing, knee range of motion throughout the gait cycle, timing of peak knee flexion in swing.

Results. Edinburgh gait score and 3D gait analysis revealed that SEMLS improved peak knee flexion in swing and related foot clearance. Improved terminal knee angle resulted in more physiological ankle initial contact angle. In several patients with crouch gait, simultaneous surgical correction of excessive dorsiflexion in stance and improvement of peak knee extension contributed to increased knee range of motion as well.

* Corresponding Author's Email: georgii_chibirov@mail.ru.

Conclusion. The distal rectus femoris transfer allows to correct the knee kinematics in patients with stiff knee gait. We recommend performing this procedure in association with other surgical methods to manage multilevel orthopedic disorders in CP patients. In patients previously undergone triceps lengthening, rectus femoris transfer should be combined with correction of excessive ankle dorsiflexion in stance to avoid iatrogenic crouch gait.

Keywords: cerebral palsy, single-event multilevel orthopedic surgery, stiff knee gait

INTRODUCTION

Stiff knee gait (SKG) is common in ambulatory children with cerebral palsy (CP) classified as GMFCS I and II [1]. This specific pattern results from permanent activity of the rectus femoris muscle during gait cycle or increased activity of the muscle in the swing phase [2]. It is associated with reduced peak knee flexion (PKF) and delayed time of PKF as well as limited knee range of motion (KROM) throughout gait cycle [3, 4].

The 3D-gait analysis permitted to detect and define this pattern, and to justify the procedure of distal rectus femoris transfer to knee flexors (m. semimembranosus, m. sartorius or m. biceps femoris). This surgery increases knee flexion during the swing phase and improves foot clearance. Distal rectus femoris transfer (DRFT) removes the action of this biarticular muscle from knee extension shifting its action posterior to knee joint axis and preserves its function as a hip flexor [4, 5].

The 3D gait analysis is recognized crucial in diagnosis of the stiff knee gait. It is mandatory in planning for this kind of orthopedic surgery [2, 6]. In literature, the results of this procedure are studied separately from other aspects often surgical and functional outcomes [7-10]. There are few publications reporting results of DRFT performed in association with other surgical procedures [11-13]. Surgical approaches in stiff knee gait associated with excessive ankle dorsiflexion in stance remain controversial.

Objective of the study was assessing the results of single-event multilevel orthopedic surgery in patients with cerebral palsy with stiff knee gait when the distal rectus femoris transfer was primary but the not only surgical element.

MATERIAL AND METHODS

This study was a retrospective review of ambulatory patients diagnosed with spastic CP having stiff knee gait who were operated on with SEMLS. The other inclusion criteria used for patient selection were medical history for 1 and more year of follow-up; spastic diplegia classified as level I, II or III of the GMFCS. Exclusion criteria were baclofen pump, botulinotherapy within the preceding 6 months, orthopedic lower limb surgery within the preceding 12 months, patients having other gait patterns.

In total, studied cohort included 20 patients (F/M = 8/12) with mean age 17.1 ± 2.94 years. Their gait was characterized by reduced foot clearance, toe drag, excessive abduction in swing. The Duncan-Ely test was positive or extremely positive (++/+++). Sixteen 16 patients were classified as GMFCS II, 4 patients were GMFCS III.

Ten patients previously underwent overlenghtening of triceps by Achilles tendon lengthening (6 patients) or by percutaneous Ulzibat fibromyotomies (4 patients). Strayer procedure associated with medial hamstring release was done in the remaining 10 patients. The time period between previous surgeries and our interventions was, at least, 4 years 3 months.

Generally, one surgical event included an average of 5.5 elements (Table 1). It reflects multiple orthopedic disorders observed in older children and young adults having stiff knee gait and bilateral surgical approach.

Table 1. Elements of SEMLS

Element	Number
Medial hamstring lengthening, gracilis release	12
Adductor tenotomy	4
Strayer, Vulpius procedure or Achilles tendon lengthening	2
Shortening of tibialis posterior tendon	6
DRFT	40
Patellar advancement	29

* significant difference in comparison to preoperative value by Wilcoxon signed-ranks test for matched samples ($p < 0,05$).

Gait analysis using the Edinburgh score [14] was performed before surgery and at a minimum of 1.5 years after surgery. Three-dimensional gait analysis was also carried out on all subjects walking barefoot. Kinematic and kinetic variables were evaluated before surgery and at the last follow-up control. We used 6-camera Qualisys Oqus system and one AMTI force plate (Advanced Mechanical Technology Inc., Watertown, MA) to collect motion analysis data. In the Ilizarov Gait Analysis Laboratory the IOR model was used for markers [15], which is optimal for minimal system configuration and for appropriate kinematic analysis decreasing artefacts of skin motion. Preoperative values were compared with those measured at the last follow-up.

AtteStat 12.0.5 software was used for the statistical analyses. The statistical values described the mean and standard deviation. The Edinburgh score data and 3D gait analysis values were compared by using Wilcoxon signed-ranks test for matched or independent samples. The test was two-tailed with a 0.05 level of significance. This research was approved by the Ilizarov Center Review Board. The study complies with the Declaration of Helsinki statement on medical protocol and ethics. Representatives of all patients enrolled in the study provided oral and written informed consent.

Figure 1. Patient R., 15-year-old boy, level II GMFCS, photographs before surgery (upper row), photographs in 1.5 years after surgery (lower row): initial contact (a); midstance (b); terminal stance (c); toe off (d); midswing (e); terminal swing (f); initial contact (g).

RESULTS

Mean values of Edinburgh scale in preoperative period and at the final follow-up visit are shown in Table 2. Generally, the SEMLS allowed an overall improvement of gait parameters. The mean total score was reduced from 22.0 to 9.8. The most significant ameliorations were

observed in swing, namely, improvement of peak knee flexion, foot clearance and knee terminal swing position, and foot progression in stance (Figure 1). On the other hand, delayed heel lift related to previous triceps lengthening procedures did not improve in postoperative period. We found no significant changes in pelvis and trunk kinematics in postoperative follow-up as well.

Table 3. Kinematics and kinetics of ankle joint, percentage of stance phase of gait cycle

Gait Profile Score		PKF; °		Timing of PKF; %		KROM; °	
Before surgery	In long-term FU	Before surgery	In long-term FU	Before surgery	In long-term FU	Before surgery	In long-term FU
14.2 ± 2.8	12.3 ± 1.3	44.2 ± 6.7	54.8 ± 5.7	91.4 ± 4.5	81.6 ± 3.1	21.3 ± 10.4	42.8 ± 7.2*

* significant difference in comparison to preoperative value by Wilcoxon signed-ranks test for matched samples ($p < 0,05$).

Figure 2. Knee kinematics of a 17-year-old boy undergone bilateral DRFT, Evans procedure and shortening of tibialis posterior tendon to achieve normal foot progression angle: reduced and delayed PKF in swing and excessive left knee flexion in stance before treatment (a); normal knee flexion instance, physiological KROM, but slightly delayed PKF in swing after surgery (b).

The changes in spatio-temporal parameters, kinetics and kinematics revealed by 3D gait analysis are shown in Table 3.

Statistically significant improvement in KROM after surgery was due to increased PKF in swing but also to reduced or even normalized knee flexion in stance (Figure 2). We explain the last amelioration by correction of excessive ankle dorsiflexion in stance. Physiological angle of stance dorsiflexion did not require compensatory knee flexion in stance phase.

DISCUSSION

Instrumented three-dimensional analysis of gait helped in the understanding of pathological patterns and the lever arm dysfunction in patients with CP [1, 11, 16]. This analysis demonstrated objective and quantifiable information regarding permanent or inappropriate rectus muscle spasticity and its detrimental effect at the knee kinematics in stiff knee gait pattern patients causing reduced foot clearance, toe drag, circumduction, and impaired limb advancement [3-5].

Rectus femoris transfer in patients with stiff knee gait increases knee flexion and decreases time to PKF during the swing phase, thereby foot clearance is improved [4, 9, 18]. On the other hand, this procedure preserves its function as a hip flexor which is needed during the first 20% of the swing phase [4, 17].

In literature, the DRFT ensures an increase PKF varying from 1.2° to 17° [2, 4, 9, 12, 19]. In our series, mean elevation of PKF was slightly over 10°, that conforms to reported results. The outcomes in PKF are controversial in long term follow-up. Saw et al. [19] reported that increased PKF remained stable within mean follow-up of 4.6 years. In contrast to that, Saraph et al. [20] reported loss of 5° during 3 postoperative years. Thawrani et al. [2] demonstrated 6° loss of PKF in 10-year follow-up in comparison to the short follow-up time.

The selection of patients for DRFT should be rigorous. The patients classified as level I or II demonstrates better outcomes in comparison to patients with GMFCS level III [6, 12]. Thawrani et al. [2] suggest that the patients who will benefit the most from surgery are those with PKF less than 64° and time to PKF more than 80% [2].

The place of DRFT in multilevel surgery should be discussed as well. It was highlighted that rectus transfer performed in association with medial hamstring lengthening improves PKF in swing phase and prevents progressing of crouch gait [4, 5]. Results of our series demonstrated both amelioration of PKF and improvement of knee extension in stance if DRFT was associated with hamstring lengthening and correction of lever arm dysfunction.

Be Morais et al. [6] discuss the risk of quadriceps weakness due to DRFT and related flexed knee walking. Their study revealed increased knee flexion angle in stance after multilevel surgery in both patients undergone RFDT and patients without rectus transfer. The patients with GMFCS III were more prone to increased knee flexion in stance after DRFT [6]. Carney et al. [21] reported higher risk of crouch gait after rectus transfer in children who used walker or crutches (GMFCS III). For Gage et al. [5], lever arm dysfunction caused by torsional deformities resulted in poor outcomes in DRFT procedures. Thus, we find mandatory to perform rectus transfer in conjunction with hamstring lengthening, excessive dorsiflexion correction and torsional deformity alignment to avoid secondary crouch gait [12, 13].

In patients of our series, excessive dorsiflexion in stance due to weakness of triceps was caused by previously performed Achilles tendon lengthening or percutaneous fibromyotomies (Uzibat method) [22]. The correction of excessive dorsiflexion, excessive external foot progression angle in combination with stabilization of the foot shape resulted in preservation of the knee-extension plantar-flexion coupling. We combined the DRFT with shortening of Achilles tendon, shortening of tibialis posterior tendon, talo-navicular arthrodesis, Evans procedure, detorsion osteotomies [23, 24]. This strategy has been showed justified. We found no patient with flexed knee gait after distal rectus transfer in the series.

CONCLUSION

1. Rectus femoris transfer in children with CP with stiff knee gait ensures increasing of knee flexion during the swing phase, knee range of motion throughout gait cycle, and improving foot clearance.
2. We recommend performing DRFT as a part of single-event multilevel surgery.

3. If stiff knee gait is associated with iatrogenic excessive ankle dorsiflexion, the surgery must include rectus transfer and simultaneous correction of excessive passive dorsiflexion, lever arm dysfunction and weakness of triceps. This strategy is intended to avoid secondary crouch gait.

ABSTRACT

Introduction. Crouch gait in cerebral palsy is characterized by excessive knee and hip flexion as well as excessively dorsiflexed ankle throughout stance. We report the results of single-event multilevel orthopedic surgery in natural and iatrogenic crouch gait.

Material and methods. A total of 39 patients (F/M = 10/29) with a mean age 16.3 years (range 7.1 to 26 years) who presented with crouch gait were operated on with single-event multilevel orthopedic surgery (SEMLS). The mean follow-up period was 21 months (range 14-36 months). According to the GMFCS, 4 patients were GMFCS I, 16 patients were GMFCS II, 19 patients were GMFCS III.

Cases were analyzed in two groups: group 1 (15 patients, no previous surgery, naturally developed crouch gait) and group 2 (24 patients with previously overlengthened triceps by illimited Achillis tendon lengthening or by percutaneous Ulzibat fibromyotomies, condition resulted in iatrogenic crouch gait). Participants underwent Edinburgh visual gait score and 3D computed gait analysis before and approximately 20 months after surgery.

Results. Edinburgh gait score revealed that SEMLS improved ankle and knee kinematics in stance and swing phases for both groups, namely, decrease of excessive dorsiflexion in stance, improvement of peak knee extension and foot progression angle as well as knee terminal swing position. The 3D gait analysis displayed an improvement in various gait outcome measures postoperatively. The mean gait profile score reduced from

* Corresponding Author's Email: dti025fd@mail.ru.

17,1 to 13,4 in natural crouch gait, and from 15,9 to 14,8 – in iatrogenic gait group. This significant improvement was due to elimination of lever arm disfunction in sagittal and transverse planes. On the other hand, there was no elevation of ankle power generation during terminal stance in both groups at the latest follow-up control.

Conclusion. Crouch gait pattern is multifaceted and associates various orthopedic disorders requiring a reconstructive surgery. There is significant difference between natural and iatrogenic crouch gait. The iatrogenic caused by surgical over-lengthening of triceps is not necessarily associated with lever arm dysfunction on the transverse plane. Given that cause of crouch gait is multiple and difficult to identify, instrumented 3D gait analysis has an important role in clinical decision-making.

Keywords: cerebral palsy, single-event multilevel orthopedic surgery, iatrogenic crouch gait

INTRODUCTION

Cerebral palsy (CP) is a major source of motor disability in childhood globally [1, 2]. While the primary neural impairment is stable, the secondary orthopedic manifestations are progressive. Crouch gait is one of the most common gait deviations observed in CP. The prevalence of crouch gait is higher in older children, adolescents and adults with levels I-III of the GMFCS [3-7]. Rodda et al. described the pattern of crouch gait as an abnormality of gait (group IV) with permanent ankle dorsiflexion and excessively flexed knee joint in stance phase [8]. Being prevalent gait pattern in CP children, the crouch gait is characterized by excessive knee flexion (knee flexion is over 20° at initial contact and over 30° throughout the stance phase) and permanent ankle dorsiflexion during stance phase [4, 8-10]. Lever arm dysfunction caused by skeletal deformities contributes crouch gait a lot. There include increased femoral neck anteversion, patella alta, planovalgus foot deformities, external tibial torsion [11-13].

The progressive knee flexion over the time is part of the natural history of this gait disorder. It results in the ground direction force to move a lot to posterior to knee joint [8]. Then, the plantar flexion/knee extension coupling fails resulting in severe walking impairment, furthermore, adolescents refuse standing and walking. Once crouch gait established, progressive knee and hip contractures, breaching of the mid-foot, valgus hind-foot, patella alta, pain syndrome in anterior knee and foot due to early onset arthritis, torsional deformity causing lever arm dysfunction, weakness and poor selective motor control combined with deleterious effects of the adolescent growth spurt result in refuse to stand and loss of walking ability [9, 14-21].

The single-event multilevel orthopedic surgery becomes mandatory to correct secondary orthopedic issues of CP. It addresses contractures and lever arm dysfunction simultaneously ensuring only one prime period of rehabilitation and reducing number of hospital admissions, surgeries and general anesthetic procedures [5, 22-28]. Planning of multi-level surgery requires preoperative 3D Gait Analysis) and considering its results with clinical and radiological findings [23, 29].

Presence and degree of orthopedic disorders vary in CP patients with crouch gait [5, 8, 22, 30, 31]. Furthermore, the natural and iatrogenic (surgeon-induced) crouch gait patterns have been distinguished. The first one occurs as an element of natural history of gait progression in CP children and onsets around puberty. The iatrogenic crouch gait is caused by

excessive calf-lengthening procedures, lengthening of spastic muscles without fixed contractures (e.g., Ulzibat percutaneous fibromyotomies) [10, 22, 32, 33]. Iatrogenic crouch gait represents a serious issue due to the limited possibilities to manage this condition including excessive dorsiflexion.

The first aim of this prospective study was to evaluate the effectiveness of SEMLS on the walking outcomes in CP patients with crouch gait. The second aim was to reveal the differences between natural and iatrogenic crouch gait patterns in preoperative period and compare outcomes in those two groups.

MATERIAL AND METHODS

This study was a retrospective review of ambulatory patients diagnosed with spastic CP having crouch gait who were operated on with SEMLS at a single institution in the period 2015-2018. The other inclusion criteria used for patient selection were medical history for 1.5 and more year of follow-up; spastic diplegia classified as level I, II or III of the GMFCS. GMFCS level was determined by physical examinations and medical records. Exclusion criteria were baclofen pump, botulinotherapy within the preceding 6 months, orthopedic lower limb surgery within the preceding 12 months, patients having other gait patterns.

In total, studied cohort included 39 patients (F/M=10/29) with mean age 16.3 years (range 7.1 to 26 years). Patients were divided into two groups. Group 1 (15 patients) included patients never operated with naturally developed crouch gait. Patients who previously underwent overlengthening of triceps by Achilles tendon lengthening or by percutaneous Ulzibat fibromyotomies formed Group 2. That group 2 of iatrogenic crouch gait consisted of 24 patients.

Gait analysis using the Edinburgh score [34] was performed before surgery and at a minimum of 1.5 years after surgery. Three-dimensional gait analysis was also carried out on all subjects walking barefoot. Kinematic and kinetic variables were evaluated before surgery and at the last follow-up control. We used 6-camerax Qualisys Oqus system and one AMTI force plate (Advanced Mechanical Technology Inc., Watertown, MA) to collect motion analysis data. In the Ilizarov Gait Analysis Laboratory the IOR model was used for markers [35], which is optimal for minimal system configuration and for appropriate kinematic analysis decreasing artefacts of skin motion. The Delphi consensus was applied to classify observed pathologic gait patterns [50]. Preoperative values were compared with those measured at the last follow-up.

AtteStat 12.0.5 software was used for the statistical analyses. The statistical values described the mean and standard deviation. The Edinburgh score data and 3D gait analysis values were compared by using Wilcoxon signed-ranks test for matched or independent samples. The test was two-tailed with a 0.05 level of significance. A chi-squared test was used to assess the difference in prevalence of the GMFCS level III cases in compared groups.

This research was approved by the Ilizarov Center Review Board. The study complies with the Declaration of Helsinki statement on medical protocol and ethics. Representatives of all patients enrolled in the study provided oral and written informed consent.

RESULTS

The Table 1 represents distribution of cases between groups depending on age, GMFCS level and gender.

Table 1. Age, gender and GMFCS level of patients

Group	n	F/M	age; years	GMFCS level; n		
				I	II	III
1	15	4/11	18.9 ± 4.75	-	4	11
2	24	6/18	14.8 ± 3.07*	4	13	7#

*- significant difference between groups ($p = 0.013$).

#- significant difference in distribution of GMFCS level III between groups ($p = 0.0301$).

Comparison of groups revealed that in group 2 (iatrogenic crouch gait) the patients were indicated for SEMLS and surgeries have been done in earlier age than in group 1. Furthermore, the prevalence of patients using crutches or walker for ambulating (GMFCS level III) was significantly higher in naturally developed crouch gait. We may speculate that the previously done triceps lengthening contributes to progression to crouch gait pattern even in mild and moderate forms of CP.

Generally, one surgical event included an average of 7.7 elements (Table 2). It reflects multiple orthopedic disorders observed in older children and young adults having crouch gait.

Table 2. Elements of SEMLS in groups

Surgery element	Group 1	Group 2 (iatrogenic crouch)
Medial hamstring lengthening	30	48
Adductor tenotomy	8	4
Strayer, Vulpius procedure or Achillis tendon lengthening	28	7
Shortening of the m.tibialis post. Tendon	18	28
Distal femoral extension osteotomy	8	18
Patellar advancement	22	42
Detorsion osteotomy of femur	6	8
Distal transfer of m.rectus femoris	2	8
Psoas release	4	-
Detorsion osteotomy of tibia	2	1
Talo-navicular arthrodesis	8	8
Evans procedure	4	12
Triple foot arthrodesis	6	16
Transfer of m.peroneus longus to calcaneus	-	7
Shortening of Achillis tendon	-	12
Release of m.tibialis ant./lengthening of m.tibialis anterior	-	2
Bunion correction/ I metatarsophalangeal arthrodesisC	11	20
Total	155	241

There was an evident difference between groups in prevalence of some specific surgical elements. In particular, the shortening of Achillis tendon and transfer of m.peroneus longus to calcaneus have been performed only in group of iatrogenic crouch in order to try restoration power for plantar flexion and to resist to excessive ankle dorsiflexion in stance. In contrast to that, in group 1, the Strayer or Vulpius procedures were done to correct equinus in 28 cases,

in group 2 those elements were encountered only in 7 patients. The distal femoral extension osteotomy, different foot arthrodesis, detorsion osteotomies and patellar advancement were noticed as common in both groups.

Mean values of Edinburgh scale in preoperative period and at the final follow-up visit are shown in Table 3. Generally, the SEMLS allowed an overall improvement of gait parameters in groups 1 and 2. The mean total score was reduced from 43.7 to 20.9 in group 1 and from 40.8 to 19.2 in group 2. The most significant ameliorations were observed in stance, namely, reduction of excessive ankle dorsiflexion, normalization of foot progression angle and knee terminal swing position (Figure 1, Figure 2). On the other hand, we found no significant changes in pelvis and trunk kinematics assessed by Edinburgh gait scale.

Table 3. Mean values of Edinburgh scale preoperative parameters in comparison to values of long-term follow-up

Parameters	Group 1		Group 2

*- significant difference in comparison to preoperative value by Wilcoxon signed-ranks test for matched samples, ($p < 0,05$).

The changes in spatio-temporal parameters, kinetics and kinematics revealed by 3D gait analysis are shown in Tables 4, 5, 6.

Preoperative assessment demonstrated specific elements of crouch gait including excessive ankle dorsiflexion, flexed knee in stance and the lack of power generation at the push-off. It should be pointed out that external foot progression angle was less excessive in group of iatrogenic crouch. Statistical analysis revealed a significant effect of SEMLS on ankle position at initial contact and on peak ankle dorsiflexion (mean decrease up to 39% in group 1 and 32% in group 2). The foot progression angle has been improved or even normalized in both groups as well. On the other hand, we found no significant elevation in the parameter of maximum ankle power generation over the time.

Figure 1. Patient Kh, 16-year-old boy, level II GMFCS, group 1, photographs before surgery (upper row), photographs in 2 years after surgery (lower row): terminal swing position (a); initial contact (b); midstance (c); terminal stance (d); preswing (e); toe off (f); midswing (g); terminal swing (h); monopodial stance (i), AP view, excessive external foot angle progression (before surgery), normal foot angle progression (after treatment).

Figure 2. Patient Z, 7-year-old boy, level II GMFCS, group 2, photographs before surgery (upper row), photographs in 2 years after surgery (lower row): terminal swing position (a); initial contact (b); midstance (c); terminal stance (d); preswing (e); toe off (f); midswing (g); terminal swing (h); monopodial stance (i), AP view, excessive external foot angle progression (before surgery), normal foot angle progression (after treatment).

Hip rotation in stance; °	26,3 ± 11,48	14,1 ± 18,2	19,2 ± 16,7	17,3 ± 14,87
Pelvic tilt; °	14,4 ± 9,53	20,8 ± 5,18	17,8 ± 10,6	22,4 ± 12,7

Knee joint improved significantly passing from the preoperatively excessive flexed position to a more physiological position during the stance phase (Table 5). Kinetic data showed reduction of knee joint extensor moments and power maximum values, approaching the normal values. The knee joint flexor moments increased significantly reflecting the correction of lever arm dysfunction in sagittal plane.

After surgery the hip femur was in a more physiological position, but the pelvic tilt increased slightly in both groups. No changes were displayed in assessment of maximum femur extension in stance. Detorsion osteotomy of femur allowed to improve the average of knee progression angle in group 1 (Table 6). In group 2, the values of that parameter were more physiological and required to correct them rarely. The reduction of GPS in both groups corresponded to overall improvement of gait parameters over times.

DISCUSSION

The widely recognized classification of gait patterns based on sagittal plane kinematics defines crouch gait as a symmetric gait with excessively dorsiflexed ankle throughout stance phase and excessively flexed knee and hip [8]. The crouch gait represents a part of a large group of flexed-knee gaits encompassing jump gait, apparent equinus gait and crouch gait when the knee flexion at initial contact is 15° more (it corresponds to 1SD above the mean value of the parameter in a healthy 6-year-old child [Haumont, 5, 9, 22]. But excessive ankle

dorsiflexion and excessive knee flexion throughout stance phase are specific qualitative criteria of the crouch pattern [5, 8].

Abnormalities observed in crouch gait are well-known and include spasticity or contracture of knee and hip flexors, increased femoral anteversion, planovalgus foot deformities, patella alta, quadriceps weakness, and external tibial torsion [8, 11, 36]. Skeletal abnormalities result in lever arm dysfunction with ground reaction vector progressing from anterior to the knee to posterior to the knee [11, 12, 20, 37]. The biomechanics of this pathologic gait pattern is more complex in that sagittal plane deformities interact with transverse and coronal plane deformities in addition to muscle weakness and impaired selective motor control [19].

The crouch gait pattern may be considered as a part of the natural history of pathologic gait progression in spastic diplegia. This pattern is specific in children older than 12 years and related to the imbalance between body mass and muscle strength during puberty [14, 21]. Crouch gait can appear as a shift from equinus or jump gait due to the development of foot deformities associated with deleterious effects of pubertal growth spurt [8]. In crouch gait, the 3D gait analysis can reveal the presence of stiff knees [8]. Furthermore, quadriceps muscles are often weak in flexed-knee gait pattern [6, 8, 17, 18].

The iatrogenic crouch gait occurs after the lengthening of the triceps surae, especially the soleus by Achilles tendon surgery, without addressing of the proximal limb issues. Because after excessive isolated calf-lengthening the knee becomes overloaded and the extensor mechanism fails [22, 33]. That results in incompetence of the plantar-flexion knee-extension coupling over time [8, 20, 33, 39, 40]. From the point of view of biomechanics, the weakened soleus fails to absorb kinetic energy by eccentric contracture in midstance and to prevent early excessive knee flexion. Rose et al. reported that only lengthening of gastrocnemius fascia provides physiological ankle power generation at push-off over the long term [39].

In literature, the prevalence of crouch gait, orthopedic and surgical management aspects, operative techniques and outcomes are reported together without separating naturally developed crouch gait cases from iatrogenic crouch gait ones [14, 31, 36, 44, 45]. Our study demonstrated that patients with iatrogenic crouch gait had got indications for SEMLS and were referred to hospital at earlier age than patients with naturally developed crouch gait. Furthermore, the GMFCS level II was dominant in group of crouch gait while prevalence of patients with level III was significantly higher in group without previous calf lengthening. Thereby our findings conform to the observations of the previous authors that isolated and/or excessive calf-lengthening predispose for crouch gait in long-term follow-up even in children with moderate walking disability [25, 32, 33].

Given that the etiology of crouch gait is multifactorial, the surgical treatment is still controversial. The multiplanar and multilevel deformities and the variability in patients' clinical profiles cause decision-making difficulties regarding the choice and timing of the surgery [4, 5, 10, 15]. The actual standard of management of crouch gait is SEMLS allowing correction of primary and secondary deformities and related to them lever arm dysfunction. SEMLS minimizes the number of surgical events and hospitalizations for children and adults with crouch gait, reduces overall recovery and rehabilitation time [23, 30, 31, 46-48].

The use of instrumented 3D gait analysis in this population allows to determine elements for orthopedic surgery, to quantify the amount of correction and to decrease the incidence of deformity recurrences after SEMLS [7, 47].

Our study revealed the features of iatrogenic crouch gait distinguishing it from naturally developed one. Postoperative weakness of plantar flexors persisting in long-term follow-up was rarely associated with torsional abnormalities and excessive knee or ankle progression angle in stance. We conclude that rotational malalignments and fixed foot deformities have no important influence for progression of the iatrogenic crouch gait.

The mean peak knee flexion in swing was more evidently decreased in group of iatrogenic crouch gait. We suppose that the presence of stiff knee represented a compensating biomechanical element in patients with mild and moderate motor disorders (GMFCS level I, II). On the other hand, there were no significant differences between groups regarding kinematics in sagittal plane in stance phase. There was a significant reduction in the maximum ankle power generation at toe-off in both groups.

So, results of gait assessment in our series demonstrate the deleterious long-term effect of the early-age interventions for triceps lengthening (percutaneous Achillis tendon lengthening, mini-invasive Ulzibat fibromyotomies) [32, 33, 43, 49]. That strategy results in permanent weakness of plantar flexors and predisposes for early onset crouch gait in ambulatory children regardless the GMFCS level.

In our series, the combination of serial history, physical examination, visual gait assessment and three-dimensional gait analysis provided quantitative measurements of the biomechanics of the pathologic gait pattern and allowed to customize a treatment algorithm.

As it has been shown in the study, the SEMLS addressing primary and secondary etiologies of crouch gait improved kinematics and some kinetic parameters in sagittal and transverse planes. There was no significant difference in final outcomes of compared groups. The reduction of GPS reflected overall gait improvement.

In previously published studies, surgical techniques, results and outcomes of the SEMLS have been reported without separated analysis of iatrogenic or naturally developed crouch gait treatment [15, 30, 37, 48]. Our approach in correction of iatrogenic crouch gait included procedures aimed to restore the plantar flexion force by shortening of Achillis tendon, transfer of peroneus longus tendon to calcaneus and foot arthrodesis in combination with correction of flexed knee contracture and detorsion osteotomy if rotational abnormalities were revealed preoperatively. This combination allowed to remove lever arm dysfunction in both sagittal and transverse planes.

However, the ankle power generation at toe-off in long-term follow-up remained still low and largely inferior to mean physiological values. Nevertheless, the correction of fixed flexed knee position, excessive external foot progression angle in combination with stabilization of the foot shape by arthrodesis resulted in restoration of the knee-extension plantar-flexion coupling and reduction of walking energy consumption. This strategy allowed to preserve ankle movement without excessive dorsiflexion. The stabilization of the foot position in sagittal and transverse planes, full knee extension with patellar advancement for increasing active knee extension force should be objectives of SEMLS in iatrogenic crouch gait management. The elevation of ankle power generation at toe-off should not be expected in older children, adolescent and adults with crouch gait, especially in iatrogenic one.

CONCLUSION

The pattern of crouch gait is multifaceted. It may be a part of natural progression in gait disorders in children with spastic diplegia. The early-age triceps lengthening predisposes to and even causes iatrogenic crouch gait. Iatrogenic crouch gait can progress without torsional abnormalities. In our study, this disorder was observed in younger population with mild and moderate motor disorders. The multilevel orthopedic surgery should be justified by 3D gait analysis and has as objective to address primary and secondary abnormalities in order to restore walking ability with lower energy consumption and without flexed-knee in stance.

ABSTRACT

Purpose of the study was to assess radiological parameters of the hip joint in patients with cerebral palsy who underwent single-event multilevel orthopedic surgery including hip reconstruction. The treatment outcomes (proximal femoral and acetabular growth) were studied depending on the age of surgery and time period between interventions in bilateral hip dislocation. The hip development after varus derotation osteotomy associated with acetabuloplasty were assessed as well as development of contralateral uninvolved hip in cases of unilateral hip displacement.

Material and methods. This study included 124 children with spastic types of cerebral palsy who underwent hip reconstructive treatment at the Ilizarov Scientific Center between 2012 and 2016. Mean age at index surgery was 7.01 ± 2.47 years (range: 3 years 7 months to 11 years 2months). Assessment of outcomes was based on AP pelvic radiographs and CT scans.

Results. Multilevel surgeries including hip reconstructions, foot reconstructions, hamstring lengthening and gastrocnemius fascia lengthening provided favorable hip development in long-term follow-up in patients with bilateral or unilateral hip subluxation. Mean increase of migration index was 3% per year after varus derotation femoral osteotomy and 2% per year after varus derotation osteotomy associated with acetabuloplasty. Progressive slow increase of Wiberg angle was observed only during 2

* Corresponding Author's Email: ahmed-tomov@mail.ru.

years after surgery. In unilateral hip disorders the contralateral release of the adductors (in case of diminished hip abduction), rigorous postural management and passive verticalization with weight-bearing ensured favorable growth and development of undislocated hip joint in long-term follow-up. The risk of hip subluxation (Reimers index over 40% or progression of Reimers index over 7% per year) increased up to 11.8% (in children younger 8 y.o.) and up to 14.3% (age over 8 y.o.) if release of the adductors of contralateral hip was not performed in unilateral hip dislocation.

Conclusion. Hip dislocation in CP children requires reconstructive surgery combining hip procedures of foot reconstructions and knee and ankle soft-tissue release in order to gain soft-tissue balance and facility to appropriate postural management.

Keywords: cerebral palsy, hip reconstruction, multilevel orthopedic surgery, outcomes

INTRODUCTION

Hip dislocation in children with severe forms of cerebral palsy is quite common pathology. This orthopedic complication occurs in 60–90% in patients with level IV–V of GMFCS levels IV–V [1]. Hip dislocation results in restriction of the ability to stand and walk, sitting imbalance, diminished hip motion, difficulty with perineal care, pain, pelvic obliquity and early onset coxarthrosis [1–3]. Moreover, unilateral dislocations attribute to scoliosis [4, 5]. Hip disorders are often associated to knee and ankle contractures, deformities of the feet. And this complex severe problem impairs quality of [6–8].

It is known that correct postural management including passive weight-bearing verticalization is favorable for development of the hip joints [9]. It has also been reported that the neck shaft angle (NSA) increases over time after a varus derotation osteotomy (VDRO) and re-dislocations must be expected in 6–7% of cases [3]. Therefore, some authors suggest that higher GMFCS levels require a higher degrees of NSA correction associated with extensive soft-tissue release [3, 10–13]. Regarding development of the operated hip in long-term follow-up, few radiological parameters have studied: NSA (°), Wiberg angle (°), acetabular angle (°) and Reimers index (migration percentage; %) [11, 14–16].

However, in reported series, the hip reconstruction procedures were performed without surgeries for associated orthopedic disorders. The authors of above-mentioned publications do not consider the role of simultaneous corrections of knee and ankle contractures and foot deformities. Whereas only realignment of the whole leg allows to apply longitudinal charge during the passive verticalization in postural management.

The aim of the study was to assess radiological parameters of the hip joint in patients with severe spastic cerebral palsy who underwent single-event multilevel orthopedic surgery including hip reconstruction. The treatment outcomes (proximal femoral and acetabular growth) were studied depending on the age of surgery and time interval between operations in bilateral hip subluxation/dislocation.

MATERIAL AND METHODS

In the present study, we included 124 children with spastic CP who underwent hip reconstruction during the period 2012–2016 in the Russian Ilizarov scientific center.

Inclusion criteria in the study were as follows: children affected with spastic CP, manifesting subluxated or dislocated hip and who underwent hip reconstructive procedure (VDRO added with acetabuloplasty if needed) in combination with simultaneously performed single-event multilevel surgery for knee and ankle contractures and foot deformities. The other inclusion criteria were clinical and radiological follow-up at least 3 years, level III, IV and V of GMFCS.

Exclusion criteria in the study were as follows: varus osteotomy in patient without CP, valgus osteotomy in CP. In total, four patients were excluded from the study.

Pre-, post-operative and the latest follow-up radiographs were analyzed for Reimers index, Acetabular index, NSA by a consultant orthopedic surgeon. Wiberg angle was measured only on post-operative and latest follow-up radiographs.

Considering the influence of the age of surgery on the prognosis for further hip joint development, radiological findings were assessed separately for the group of patients under 8 y.o. (Group I) and for the group of children aged 8 and more years (Group II). In patients with bilateral surgery, each hip was reviewed independently, except for age analysis.

Within these two big groups we distinguish subgroups for fine radiological analysis:

- Bilateral subluxation and/or dislocation who underwent bilateral consecutive hip reconstruction within period less 6 months – subgroups Ia and IIa. Each hip was reviewed independently, except for age analysis.
- Unilateral subluxation or dislocation – subgroups Ib and IIb - radiological analysis for operated hip;
- Unilateral subluxation or dislocation – subgroups Ic and IIc - radiological analysis for uninvolved hip (Reimers index less 40%);
- Bilateral subluxation and/or dislocation where the second hip was operated in 1 year more after index surgery because of a somatic disorder – subgroup Id;

No cases corresponding the criteria for subgroups IId were found in the cohort.

Prior to surgical intervention, computed tomography (CT) scans with 3D reconstructions were acquired at a thickness of 1 mm to visualize the direction of migration, sphericity of the femoral head and to determine the sector of the maximal acetabular dysplasia. In 15 patients the lack of acetabular cover was measured comparing pathological findings to normal values of a given age [17]. Thus, the required amount of correction by acetabuloplasty was determined prior to surgery (Figure 1).

During surgery the height of bone graft after femoral shortening was tailored depending on the needed size for inter-position on the pelvic osteotomy side. Our approach ensured the amount of correction adjusted to the individual situation.

All the surgeries were performed by the same senior surgeon, an author of this chapter, who has regularly practiced these procedures with these two types of plates during the previous 5 years. He was always assisted by full staff member surgeons. The technique femoral and pelvic osteotomies, soft tissue procedures were standard [18-20].

Postoperatively, bilateral short leg plasters with a connecting bar were applied for six to eight weeks. All patients were passively verticalized in standers in 14 to 21 days after the intervention. At discharge, recommendations were given on orthosis fitting, postural management, joint mobilization. Consultations were scheduled at regular basis.

Figure 1. CT scan showing the measurement of the lack of acetabular cover: measurement in coronal plane, dysplastic acetabular angle (1), normal virtual acetabular angle (2), distance between two oblique lines measured from the acetabular edge represents the lack of acetabulum in coronal plane (3) (a); measurements in sagittal plane, the virtual line (3) making normal angle obliquity (12°) of acetabulum edge in sagittal plan and taking into consideration amount of acetabulum correction (line 2, distance of 0.43 mm in middle sector of acetabulum) representing the most important acetabular dysplasia of 0.72 mm in posterior sector of acetabulum (b).

Statistical assessment was performed with AtteStat® software. Mean values of indices and their errors were defined for descriptive statistics. The comparisons between the groups in the quantitative study were carried out using Wilcoxon signed-ranks test for matched or independent samples. The test was two-tailed with a 0.05 level of significance.

This research was approved by the Ilizarov Center Review Board. The study complies with the Declaration of Helsinki statement on medical protocol and ethics and the “Rules of Clinical Practice in the Russian Federation” approved by Order of the Ministry of Health of the Russian Federation of June 19, 2003 No. 266. Representatives of all patients enrolled in the study provided oral and written informed consent.

RESULTS

Two hundred seventy-three pediatric patients were treated operatively for neurologic reconstructable hip dysplasia at our institution between 2012 and 2015. Out of 273 patients with cerebral palsy, 149 did not meet our inclusion criteria.

One hundred twenty-four patients (81 males and 43 females) were included in our study. One hundred nineteen patients (95.97%) were non-ambulatory (GMFCS IV or V) and 5 patients (4.03%) were walkers (GMFCS III) (Table 1). The mean age at the index surgery was 7.01 ± 2.47 years (range: 3 years 7 months to 11 years 2months). According to GMFCS levels, the distribution was as follows: level III – five patients, level IV – 70 patients, level V – 49 patients.

All radiographic parameters were significantly improved compared with pre-operative values in subgroups Ia and IIa (Table 2, Figure 2).

In the long-term follow-up, in subgroups Ia and IIa, the centered position of the femoral head was maintained. The values of Wiberg angle corresponded to the normal development of acetabulum. Slight elevation of the NSA was 1° to 2° per year. Mean Reimers index remained within normal range except 2 cases (two hips, 1.9%) in group 1a where this parameter exceeded 30% in 3 years after surgery with annual progression of more than 10%. In both fair cases, there was not any postural management and orthosis fitting.

Table 1. Patient distribution across GMFCS levels, elements of surgery

		Group I (age under 8 years)		Group II (age of 8 years and older)	
		Bilateral subluxation/dislocation	Unilateral subluxation/dislocation	Bilateral subluxation/dislocation	Unilateral subluxation/dislocation
Number of patients		52	31	20	21
Mean age at index surgery; years		5.8 ± 1.03	5.3 ± 1.17	9.6 ± 1.67	10.0 ± 2.41
GMFCS, n	III	-	2	1	2
	IV	33	13	12	13
	V	19	17	7	6
Surgical elements; n					
VDRO		104	31	40	21
Acetabuloplasty		40	15	14	12
Open hip reduction		3	-	4	-

Figure 2. Bilateral hip dislocation, 5 y.o. girl, GMFCS V: before surgery, Reimers index 100% (right hip), 100% (left hip), acetabular index 29° (right hip), 30° (left hip) (a); after surgery Reimers index 0% (right hip), 0% (left hip), acetabular index 12° (right hip), 13° (left hip), Wiberg angle 37° (right hip), 36° (left hip) (b); in 1 year after surgery Reimers index 0% (right hip), 0% (left hip), acetabular index 12° (right hip), 12° (left hip), Wiberg angle 34° (right hip), 32° (left hip) (c); in 3 years after surgery Reimers index 0% (right hip), 0% (left hip), acetabular index 11° (right hip), 12° (left hip), Wiberg angle 30° (right hip), 30° (left hip) (d).

Table 2. Pre-operative, post-operative and long-term FU radiographic parameters in subgroups Ia and IIa

	Subgroup	Preoperative	Early postoperative	1-year FU	2.5 to 3 years FU
Reimers index; %	Ia	61,2 ± 25,8	2,0 ± 10,6*	3,3 ± 6,6*	6,1 ± 9,6*
	IIa	62,4 ± 22,7	0,4 ± 1,7*	3,2 ± 5,7*	3,7 ± 4,6*
Acetabular index; °	Ia	30,8 ± 8,1	23,1 ± 6,8	22,6 ± 7,3	22,4 ± 15,8
	IIa	29,4 ± 6,1	20,4 ± 7,7	18,9 ± 6,9	20,0 ± 4,6
NSA; °	Ia	161,1 ± 10,1	119,8 ± 8,2*	120,2 ± 15,1*	122,8 ± 15,3*
	IIa	158,1 ± 12,4	118,6 ± 6,9*	117,7 ± 9,6*	121,2 ± 9,0*
Wiberg angle; °	Ia		25,8 ± 6,8	27,0 ± 7,9	30,3 ± 7,9
	IIa		32,8 ± 6,7	37,6 ± 16,0	34,9 ± 7,0

*- significant difference in comparison to initial value, Wilcoxon signed-rank test ($p < 0.05$).

In unilateral subluxation, the final outcomes were good, with stable centered hips (Reimers index less 30%) in all operated hips (Table 3, Figure 3). The mean Wiberg angle corresponded to the favorable development of the hip. Slight elevation of the NSA did not exceed 7% per year and remained within normal values.

Table 3. Pre-operative, post-operative and long-term FU radiographic parameters in subgroups Ib and IIb

	Subgroup	Preoperative	Early postoperative	1-year FU	2.5 to 3 years FU
Reimers index; %	Ib	72,3 ± 23,7	1,5 ± 8,6*	2,9 ± 6,2*	5,3 ± 7,7*

	IIb		32,6 ± 7,9	27,8 ± 8,6	29,2 ± 7,7

*- significant difference in comparison to initial value, Wilcoxon signed-rank test ($p < 0.05$)

Figure 3. Unilateral left hip subluxation, 6 y.o. boy, GMFCS IV: before surgery, Reimers index 26% (right hip), 64% (left hip), acetabular index 28° (right hip), 32° (left hip) (a); after surgery Reimers index 26% (right hip), 2% (left hip), acetabular index 28° (right hip), 14° (left hip), Wiberg angle 16° (right hip), 40° (left hip) (b); in 1 year after surgery Reimers index 18% (right hip), 0% (left hip), acetabular index 26° (right hip), 16° (left hip), Wiberg angle 23° (right hip), 31° (left hip) (c); in 3 years after surgery Reimers index 13% (right hip), 5% (left hip), acetabular index 19° (right hip), 18° (left hip), Wiberg angle 28° (right hip), 30° (left hip) (d).

In unilateral hip subluxation cases, among the contralateral hips, 48 hips had Reimers index of less than 20% at the 3-year follow-up (Table 4). Four of the contralateral hips (7.7% of unilateral forms) showed fast progressive increase of 12 to 23% per year at follow-up in subgroup Ic (Figure 4).

Table 4. Pre-operative, post-operative and long-term FU radiographic parameters in subgroups Ic and IIc

	Subgroup	At the index surgery	1 year FU	2.5 to 3 years FU
Reimers index;%	Ic	19,8 ± 12,2	14,9 ± 10,1	9,0 ± 6,7
	IIc	17,8 ± 10,7	21,5 ± 12,5	14,2 ± 10,9
Acetabular index; °	Ic	17,5 ± 5,3	19,5 ± 5,4	23,3 ± 6,1
	IIc	18,9 ± 6,2	18,9 ± 7,2	19,8 ± 2,9
NSA; °	Ic	162,1 ± 8,6	160,2 ± 12,9	159 ± 16,5
	IIc	158,9 ± 8,9	154,6 ± 12,2	157 ± 11,5
Wiberg angle; °	Ic	22,5 ± 8,6	31,0 ± 8,8	29,3 ± 7,1
	IIc	28,9 ± 6,6	30,9 ± 10,5	25,5 ± 2,6

Figure 4. Unilateral right hip subluxation, 6 y.o. boy, GMFCS IV: before surgery, Reimers index 52% (right hip), 12% (left hip), acetabular index 32° (right hip), 27° (left hip) (a); after surgery Reimers index 0% (right hip), 12% (left hip), acetabular index 18° (right hip), 25° (left hip), Wiberg angle 32° (right hip), 23° (left hip) (b); in 1 year after surgery Reimers index 0% (right hip), 25% (left hip), acetabular index 9° (right hip), 25° (left hip), Wiberg angle 32° (right hip), 19° (left hip) (c); in 3 years after surgery Reimers index 11% (right hip), 52% (left hip), acetabular index 9° (right hip), 31° (left hip), Wiberg angle 30° (right hip), 3° (left hip) (d).

Reconstructive surgery for contralateral hip was required in two cases. In all these 4 cases with high annual elevation of migration index, the limited abduction ROM has been preoperatively noted but the adductor-psoas tenotomy was not performed on the contralateral site during the index surgery. It should be noted that adductor tenotomy on contralateral hip was never required in windswept deformity.

Table 5 demonstrates radiographic parameters for hips operated on in more than 1 year after index surgery in cases of bilateral hip subluxation/dislocations. It is obvious that unilateral reconstructive surgery doesn't improve or even stabilize the radiographic parameters of the contralateral hip joint already having the Reimers index over 40% at index surgery. On the other hand, even postponed surgery provided satisfactory outcomes in long term.

Table 5. Pre-operative, post-operative and long-term FU radiographic parameters in subgroups Id

	Before index surgery	In a year (before the second surgery)	Early postoperative	In 12 months	In 2 years
Reimers index;%	60,8 ± 20,2	64,7 ± 24,0	1,02 ± 2,13*	1,2 ± 2,7*	2,8 ± 5,5*
Acetabular index; °	30,6 ± 4,7	30,5 ± 6,3	23,5 ± 5,8	20,4 ± 5,3*	19,5 ± 1,7*
NSA; °	163,8 ± 9,9	162,7 ± 10,9	121,7 ± 4,2*	120,2 ± 9,7*	120,5 ± 12,7*
Wiberg angle; °			26,9 ± 7,4	30,2 ± 9,5	28,8 ± 1,7

*- significant difference in comparison to initial value, Wilcoxon signed-rank test ($p < 0.05$)

Comparing radiographic outcomes of hip reconstructions in patients aged less 8 years and patients with age of 8 and more years, we found no difference in development of operated hip joints. Furthermore, the outpatient records revealed that none of the patients suffered from hip pain at the latest follow-up. We may speculate that simultaneous realignment of the whole leg provide favorable conditions for postural management and ensure improved hip development even after the age of 8 years in reconstructable cases.

CT morphometric analysis (Table 6) revealed amelioration of the operated hip anatomy (Table 6, Figure 5). Our approach provided a quantitative basis to calculate the amount of acetabular correction. Acetabular cover studied in a year after surgery had improved significantly towards the normal values in all 15 cases.

Table 6. CT morphometric measurements

	Acetabular anteversion	Axial acetabular index	Coronal acetabular index	Femoral neck anteversion	NSA	Sagittal acetabular inclination
Preoperative	15,86° ± 4,5°	125,2° ± 9,5°	30,9° ± 9,4°	47,3° ± 6,9°	152,1° ± 7,4°	4,9° ± 3,5°
In 10 to 14 months after surgery	14,43° ± 3,48°	120,8° ± 18,9°	20,8° ± 6,3°	22,8° ± 10,2°	118,5° ± 17,8°	12,2° ± 2,8°

Figure 5. CT scans of hip reconstruction with previously calculated amount of acetabular correction, upper row – CT scans, lower row – corresponded radiographs of the reconstructed hip: preoperative scan and radiograph (a); measurement of amount of acetabular correction – length of perpendicular line between real and virtual lines connecting Y-cartilage and acetabular edge (b); immediate postoperative scan and radiograph (c); outcome in 2 years (d).

DISCUSSION

Spastic hip subluxation or dislocation is a frequent problem in children with cerebral palsy [12-14, 16, 19]. Optimal clinical decision making and surgical management of hip disorders in children with cerebral palsy requires an understanding of the pathogenesis and natural history [21-23]. The incidence of subluxation and dislocation of the hip in children with cerebral palsy correlates with the severity of motor impairment and is accompanied by a serious deterioration in the quality of life for both the child and his family or caregivers [6, 15, 23–25].

The hip problems management in CP children surveillance should include following a surveillance program, counteracting the effects of the muscle imbalance, proper positioning with the hips in abduction and extension, botulinum therapy, surgical treatments consisting of adductor-psoas release, VDRO of the proximal femur and pelvic osteotomy [16, 26-28]. This program allows, in most cases, to prevent unreconstructable hip dislocation requiring palliative surgery.

Among the radiological parameters in assessment of the hip joint, the Reimers index is the major criterion of indication for the surgery along with the acetabular index [12, 14, 18, 21, 29, 30]. The NSA and the Wiberg index have less importance in preoperative period, but in combination with above-mentioned parameters ensure a reliable assessment of morphometric changes of the hip in long-term follow-up after surgery [11, 31].

Currently, there is a consensus on the indications for reconstructive hip surgery in CP children: the Reimers index 40% or more or the rate of its increase $\geq 7\%$ a year [21, 22, 29]. Regarding the acetabular index, its threshold values for reconstructive surgery (pelvic

osteotomy) are controversial. It is recognized, that the lateralisation of the femoral head precedes the acetabular dysplasia [1, 2, 10, 13]. Hägglund et al. reported that hip centration by non-operative treatment in patients with Reimers index 30-39% resulted in decrease of acetabular index below the threshold values of operative treatment [29].

Most commonly, combinations of adductor-psoas release, VDRO and pelvic osteotomies are used for hip reconstruction [11, 12, 18, 19, 30, 32]. The optimal age for reconstructive procedures is up to 5–7 years old as during the residual growth the favorable remodeling of the hip occurs on conditions of appropriate postural management [15, 22, 33-35].

McNerney et al. demonstrated immediate and long-term (average FU 6.9 years) results of hip reconstruction in CP children analyzing changes in Reimers index: mean postoperative decrease from 66% to 5% followed by slight elevation of 11% by the latest follow-up control [32]. Moreover, the average acetabular index decreased from 26° to 13° in the short term and continue to decrease up to 11° in the long-term FU. Karlen et al. in a series with an average follow-up of 56 months showed an evident improvement in the migration index from 84 to 8% in the short term and up to 14% in the long-term observation period [30]. Jozwiak et al. in a series of 25 patients (30 hips) achieved required hip correction. In lonr-term follow-up they observe a slight increase of radiographic parameters: acetabular index from postoperative 22° to 23° in the long term, Reimers index from 11% to 23%, Wiberg angle from 16° to 23°, NSA from 133° to 140° [19]. Reidy et al. also reported improvement of Reimers index from 63.6% to 2.7% by surgery followed. Slow increase of mean Reimers index up to 9.7% occurred in the long-term period [12]. A review of the current literature shows that there is not clear understanding what postoperative increase of Reimers index corresponds to favorable development of operated hip. Bayusentono et al. [36] found a statistically significant increase of the Reimers index of 2.0% per year in GMFCS level IV and 3.5% in level V, which corresponds to increase of 4.0% in walkers and 7.7% in non-walkers in long-term follow up of 5 years in the article of Reidy et al. [12]. In both series final outcomes were classified as good. Regarding non operated hip in CP children, the risks of subluxation are not negligible if annual increase of migration index is 4% or more for Terjesen [37], 6-7% or more for Soo et al. [38] and Connelly et al. [39]. In our series, in majority of cases elevation of Reimers index remained less than 3% a year in long-term follow-up. In 98.1% of surgeries outcomes were classified good. Thus, the progressive elevation of Reimers index less than 4% per year in post-operative period should be recognized reflecting favorable development of operated hip.

It has been shown that the NSA increases over time after a VDRO [11, 12, 19]. Davids et al. [40] reported a 29%-loss of correction in 5 years and 6 months after surgery. Miller et al. [13] recommend correcting the NSA down to 100° in non-ambulatory patients and 120° in ambulatory patients. Mazur et al. suggests a correction to a post-operative NSA down to 100°–110° at the age of 4–12 years in non-walking children with GMFCS levels IV–V considering a spontaneous increase of 20° during residual growth, for older children NSA of 110°–120° should be recommended [11].

In our series, mean change of NSA was 1°-2° per year in bilateral dislocations and 7.7° per year in monolateral hip dislocation. However, these changes were accompanied by improvement of mean Wiberg angle, that reflects harmonious development of the proximal femur and acetabulum. Progressive slow increase of Wiberg angle until normal values was observed during 2 years after surgery.

There remains controversy about the rate of re-dislocations after hip procedures. Sankar et al. reported one hip dislocation recurrence out of 14 reconstructive interventions [33].

Jozwiak et al. showed one dislocation and 6 subluxations (23%) after 30 reconstructive interventions in the long-term period [19]. Rutz et al. [41] found two hip re-dislocations in the long-term period after 168 interventions. Reidy et al. [12] stated that only 96.5% of operated hip joints were considered stable in the long-term period with a Reimers index of less than 33%. The authors explain recurrences with surgical errors. On the other hand, none of the above series of patients had SEMLS performed on knee and ankle joint, feet. Postural management, standing, orthosis fitting applied in post-operative period were not mentioned. However, postural correction using standing frames and proper positioning when sitting and lying is crucial for further hip development [9, 15, 21, 42]. Simultaneous correction of associated contractures and foot deformities seems to be necessary in order to facilitate postural management, shoes-wearing. On the short series, we showed previously the benefice of multilevel surgical approach in CP children with hip dislocation [18]. The present large series evaluating outcomes in long-term period is concordant with earlier study. Hip subluxation recurrence with rate of Reimers index of over 10% per year occurred only in two cases (2 hips, 1.9%). In both cases there was failure of postural management and lack of orthosis fitting.

Another controversial issue is unilateral hip dislocation. In literature, there is not consensus regarding contralateral hip. Carr et Gage observed lateralization of femoral head on contralateral site only in 0.9% of cases [43]. Gordon et al. did not find any critical elevation of Reimers index in the long-term follow-up [44]. Settecerci et al. had to perform VDRO of the contralateral hip only in two out of 48 children who had previously undergone unilateral hip reconstruction [45]. On the other hand, Noonan et al. operated on the contralateral hip in 15 out of 35 children in the long term after the index surgery [46]. Canavese et al. performed 12 hip surgeries on the contralateral hip in 27 children [47].

Owers et al. demonstrated more appropriate approach combining unilateral VDRO with bilateral soft tissue release to restore muscle balance [48]. Larsson et al. suggest VDRO only of dislocated hip with soft-tissue release carried out bilaterally followed with intensive non-operative treatment [16].

In our series, lateralization of contralateral hip and elevation the Reimers index were never observed on condition of bilateral adductor-psoas release. On the other hand, unilateral soft-tissue release resulted in significant deterioration of Reimers index in 7.7% in the contralateral hip. Thus, we share the opinion that children operated on with unilateral soft-tissue release have a high risk of displacement of the contralateral hip. And bilateral release of soft tissues to restore muscle balance should be mandatory in unilateral hip dislocation.

Using three-dimensional CT, Chung et al. [49] have shown the improved acetabular cover improved following a Dega osteotomy in hip reconstruction. Our approach to calculate a required acetabular edge advancement in acetabuloplasty demonstrated its reliability. Surgery with predetermined size of autograft resulted in precise correction angular acetabular parameters and improved acetabular cover.

Our long-term results show that reconstructive hip surgery in combination with SEMLS is a safe way to generate stable, pain free hips. Muscle balance, postoperative postural management, passive verticalization have crucial role for long-term normal development of operated hip. In our series this rule was not followed in 4 cases and it resulted in recurrent subluxation.

CONCLUSION

Reconstructive surgery in hip subluxation or dislocation in CP children should be combined with restoration of bilateral muscle balance, especially adductors, as well as correction of contractures of the knee and ankle joints, foot deformities in order to ensure favorable conditions for postural management in early and late postoperative period.

The rate of migration index elevation less than 4% per year corresponds to favorable development of operated hip. Combination of hip reconstruction and SEMLS ensures good outcomes even in children aged more 8 years. Bilateral release of soft tissues to restore muscle balance should be mandatory in unilateral hip dislocation.

Chapter 122

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY: HISTORICAL PERSPECTIVE

Jeffrey L. Ponsky*, MD

Cleveland Clinic, Cleveland, OH, US

INTRODUCTION

It has been nearly four decades since Michael Gauderer and I had the opportunity to first perform an endoscopically guided percutaneous gastrostomy (PEG) [1]. Prior to that time, gastrostomy was performed by means of a laparotomy in order to access the stomach. The indication for the gastrostomy usually involved the need for long term enteral feeding in patients with neurological impairment or for long term gastric decompression.

The techniques of open gastrostomy were varied but the most common was the Stamm gastrostomy. This method involved placing two concentric purse string sutures in the anterior wall of the stomach and performing a gastrotomy in the center of the sutures (Figure 1). A mushroom type catheter was then placed in the gastrotomy, the purse strings tied and the tube brought out through a small incision in the abdominal wall. Typically, the anterior gastric wall was also sutured to the parietal peritoneum to hold the stomach to the anterior abdominal wall. Other methods, such as the Janeway gastrostomy, created a tube out of the anterior gastric wall which was brought out of a small incision in the abdominal wall to create a permanent gastric stoma (Figure 2).

These methods were effective, yet the use of gastrostomy for feeding was not commonly employed as the laparotomy and anesthesia required were viewed as significant interventions in these severely debilitated patients. Moreover, the patient faced risks associated not only with the gastrostomy creation itself but also those of a midline laparotomy, including hernia formation, surgical site infection and pain.

Dr. Gauderer, a pediatric surgeon at Rainbow Babies and Children's Hospital in Cleveland, Ohio, had dealt with many children requiring long term enteral feedings and had pondered whether less invasive access to the stomach might be achieved. I was a general

* Corresponding Author's Email: ponskyj@ccf.org.

surgeon and endoscopist also at the Case Western Reserve University School of Medicine and brought both endoscopic skills and technology to the clinical problem.

Figure 1. Stamm gastrostomy model demonstrating two concentric purse-string sutures around a balloon tip catheter and four gastropexy sutures used to secure the stomach to the posterior layers of the anterior abdominal wall.

Figure 2. Janeway gastrostomy. A) Laparoscopic view of the stapled creation of a tubularized portion of stomach that is delivered to the skin surface and surgically matured. B) Endoscopic view of the anti-reflux valve and non-ballooned catheter.

Together, we conceived of the idea of using the endoscope to guide a percutaneous needle puncture of the stomach and passage of a suture. The suture would be grasped by the endoscope and pulled out of the patient's mouth. Then, a modified de Pezzar (mushroom type) catheter could be affixed to the suture and pulled through the mouth, down esophagus, into the stomach, and out of the abdominal wall. In order to provide a dilating function to the leading end of the flexible rubber catheter, a tapered plastic intravenous catheter (Medicut) was placed over the end of the tube (Figure 3) [1].

This procedure was first performed in five children by Drs. Gauderer and myself in the spring of 1979. All of the children did well and the procedure was reported in 12 children and 19 adults shortly thereafter in the *Journal of Pediatric Surgery* [1]. Modifications in the tube,

suture and the technique have followed, but the key steps of the method have remained essentially unchanged.

Initially, we placed much emphasis upon the use of trans-illumination of the abdominal wall by the light of the endoscope in order to select the best site for gastric puncture. Most practitioners have switched to the use of the “safe tract” technique which uses a finder needle to aspirate, looking for air, as the needle is advanced through the abdominal wall into the stomach. This method, described by Gregory Foutch in 1988, aimed to reduce the incidence of inadvertent puncture of adjacent viscera [2].

Figure 3. Modified de Pezzar catheter with dilating tip and pull suture as originally described for percutaneous endoscopy gastrostomy.

Figure 4. Russell introducer method of gastrostomy. Following dilation, a foley catheter is passed into the body of the stomach through a peel-away sheath.

Figure 5. Endoscopic view of a PEG with jejunal feeding extension. The extension curves in the stomach and passes post-pyloric.

Shortly after the initial description of PEG, a number of other approaches to placement of a percutaneous gastrostomy were described. These included the method published by Saks and Vine which localized the planned gastrostomy site as Dr Gauderer and I initially described, but passed a semi-stiff guidewire instead of a suture and pushed the tube down over the wire instead of pulling it [3]. Results of the ‘Pull’ and ‘Push’ methods of have been equivalent [4].

Another technique, described by Russell and Brotman, involved puncturing the stomach under endoscopic guidance, then dilating the needle tract and placing a Foley catheter into the stomach through a peel away sheath (Figure 4) [5]. This technique suffered from kinking of the dilating catheter and enjoyed only limited popularity. More recent substitution of laparoscopic type trocars to perform the puncture have somewhat revitalized the method.

Once the principle of endoscopically guided enteral access was established, numerous modifications and variations of the method were developed. Jejunal extensions of the gastrostomy tube for use in patients with gastroparesis were described by Dr Aszodi and myself. They are still used in spite of the frequent frustration with extension migration or dysfunction (Figure 5) [6]. Shike described and popularized direct percutaneous endoscopic jejunostomy (PEJ) which is performed by the same method as the PEG, but in the small bowel [7].

The development of percutaneous endoscopic gastrostomy was a small innovation using the methods of surgery and endoscopy to facilitate patient care. Perhaps more significant is the fact that this innovation heralded the beginning of the era of minimally invasive therapeutics.

EDITOR’S COMMENT

The ‘small innovation’ that Dr Ponsky quite humbly describes in this chapter was another revolutionary leap forward in the combination of surgical knowledge and endoscopic skill, similar to the development of methods for endoscopic polypectomy and control of gastrointestinal (GI) hemorrhage [8]. It stands apart from these other innovations, however, in

that he and Dr Gauderer developed an endoscopic therapy that intentionally created a full thickness GI tract defect. This not only permitted hundreds of thousands of patients to receive necessary enteral nutrition in a safe fashion each year, but was the basis upon which numerous other endoscopic and surgical therapies have been based. (EMP and JMM)

Chapter 123

INDICATIONS, CONTRAINDICATIONS, DECISION MAKING AND INFORMED CONSENT

Robert D. Fanelli*, MD and Josephine A. Fanelli†

The Guthrie Clinic, Sayre, PA, US

INTRODUCTION

Enteral hyperalimentation is the preferred method of nutritional support for patients with an intact, functional gastrointestinal tract who are unable to ingest adequate calories to meet metabolic requirements [1]. Enteral nutrition has several advantages over parenteral hyperalimentation, including reduced risks of phlebitis, bacteremia, thromboembolism, and it provides continued stimulation of the gastrointestinal tract, important for maintaining physiologic function. The costs associated with enteral hyperalimentation are reduced compared with other routes of nutritional support as well [2].

Nasogastric and nasojejunal hyperalimentation has been recommended for patients who will require 30 or fewer days of enteral feeding, reserving direct enteral access for patients expected to require longer term solutions [1]. However, nasoenteric feeding devices are uncomfortable, and most typically require continued hospitalization while in use because their tendencies toward clogging and inadvertent removal make them generally unsuitable for long-term care settings and home use. Given current emphasis on the Institute for Healthcare Improvement Triple Aim of improved patient experience, reduced per capita cost, and overall improvement in population health, nasoenteric feeding falls short [3, 4]. Therefore, percutaneous feeding tubes typically are advocated for in those with all but very short-term needs.

Percutaneous endoscopic gastrostomy (PEG) has become the preferred method for providing moderate to long-term enteral feedings since its introduction more than 35 years ago [5-7]. Owing to its cost-effectiveness, ease of placement, and relative safety as compared to surgical methods, PEG is a minimally-invasive procedure that typically can be performed

* Corresponding Author's Email: surgical.presentations@gmail.com.

† Josephine A. Fanelli, RN.

without the need for general anesthesia, making it a suitable choice for a variety of clinical conditions. In addition to enteral feeding, the PEG tube commonly is utilized as a means for hydration, medication administration, and gastrointestinal decompression for benign and malignant conditions [8, 9].

Percutaneous endoscopic gastrostomy tube placement is associated with improvements in nutritional status, maintenance of body weight, and improved quality of life for patients unable to sustain adequate oral nutrition [10]. Percutaneous endoscopic gastrostomy has been accepted widely into use in both pediatric and adult populations and has been associated with improvement in generalized failure to thrive as well as numerous specific conditions such as neurologic, malignant, and traumatic conditions among others [11, 12]. Although PEG is useful in many patients, there are specific patient populations that may not realize benefit from feeding tube placement; therefore, the decision to proceed with PEG should be individualized according to patient characteristics and clinical scenarios, and carefully considered. Several studies have reported no improvement in survival, nutritional status, or resolution of pressure wounds after PEG placement for adult patients with advanced dementia, particularly those over 80 years of age [13-15]. In these scenarios, the decision to proceed with PEG should be based on holistic appraisal of patient circumstance.

INDICATIONS

Before consideration is given to providing permanent gastrointestinal access for enteral support, individual patient characteristics and circumstances should be evaluated. These include the natural history of the underlying disease, associated diagnoses, patient comfort and quality of life, and the likelihood for meaningful clinical improvement if nutritional support is initiated and maintained [16].

Generally speaking, PEG is used to accomplish two rather broad goals in the clinical setting: Provide enteral nutrition support for patients with inadequate oral intake and a functional gastrointestinal tract; and provide gastric decompression for patients with chronic benign and malignant partial or complete obstructions of the gastrointestinal tract who are not considered candidates for operative remedy at the time of planned PEG placement [17]. These and other general indications for PEG are summarized in Table 1.

For patients with short-term nutritional or decompressive needs, a nasointestinal approach often is more suitable than PEG due to ease of placement, use, and removal. Prolonged use of transnasal access, however, is associated with mucosal erosions, gastroesophageal reflux, bleeding, aspiration pneumonitis, and chronic sinusitis [2, 18]. Therefore, while a brief trial of transnasal access is reasonable as a means of assessing feeding tolerance and short-term survival, when the likelihood of longer term need is suspected, PEG placement should be considered early in the decision-making process.

Nutritional support through PEG placement most often becomes necessary as the result of dysphagia caused by neurodegenerative disease, whether of acute onset like with stroke, or more insidious and chronic, as with amyotrophic lateral sclerosis, for example. Dysphagia secondary to neurodegenerative diseases accounts for as many as 90% of PEG placements in adults [19]. Obstructive dysphagia related to esophageal neoplasia, and recurrent pulmonary aspiration with oral feeding are other common indications for PEG placement [20]. Chapters 7-14 of this text outline specific PEG techniques and their associated results.

Table 1. General indications and common diagnoses for percutaneous endoscopic gastrostomy tube placement

Indications for PEG for enteral nutrition
<i>Neurological diseases resulting in dysphagia, increased aspiration risk</i> Cerebrovascular disease (e.g. stroke) Motor neuron diseases (e.g. Amyotrophic Lateral Sclerosis) Multiple Sclerosis Pseudobulbar Palsy Cerebral palsy Parkinson's disease Psychomotor retardation Traumatic Brain Injury Coma
<i>Malignant conditions resulting in dysphagia</i> Head and neck malignancy Dysfunction resulting from prior treatment of head and neck malignancy Esophageal malignancy Chemotherapy-induced anorexia
<i>Miscellaneous conditions necessitating enteral access</i> Failure to thrive, generalized inanition Burn injury Significant trauma not precluding oropharyngeal access Cystic fibrosis Prolonged intensive care Congenital anomalies (e.g. tracheoesophageal fistula) Facial or oral surgery Chronic renal failure Esophageal injury (perforation, caustic injury, etc.) Superior mesenteric artery syndrome
Indications for PEG for enteral decompression
<i>Benign obstruction (not amenable to stenting or operative therapy)</i> Gastric outlet obstruction Chronic small bowel obstruction, partial or complete Persistent idiopathic or cyclical nausea and vomiting Refractory gastroparesis
<i>Malignant obstruction (not amenable to stenting or operative therapy)</i> Gastrointestinal neoplasia Malignant bowel obstruction <i>Metastatic</i> <i>Locally advanced, infiltrative or compressive</i> <i>Widely spread visceral involvement (carcinomatosis)</i>

PEG increasingly is utilized for gastric decompression in patients with intractable nausea and vomiting resulting from a variety of benign and malignant conditions. Table 1 offers a listing of common indications for decompressive PEG. Chapter 15 (Alternative Uses of Percutaneous Endoscopic Gastrostomy) discusses decompressive PEG in greater detail.

CONTRAINDICATIONS

While PEG has demonstrated proven benefit for a variety of indications, each consultation must be evaluated on an individual basis for medical necessity and risk, since

some patient populations have not realized demonstrable improvements from PEG placement. In one study of patients with advanced dementia undergoing PEG placement, increased mortality rates were observed both at one-month (54%) and at twelve-months post-PEG placement (90%) [21]. Based on these data, advanced or irreversible dementia is no longer considered by these authors to be an indication for PEG. The leading potential contraindication to PEG that must be evaluated is the patient's overall clinical scenario; is there a reasonable likelihood for benefit through enhanced delivery of enteral nutrition and not be harmed during the surgical procedure? Generally accepted absolute and relative contraindications to PEG are listed in Table 2.

Since PEG was first introduced, many of its initial absolute contraindications have become relative contraindications, e.g., coagulopathy that routinely is reversed rapidly prior to PEG placement. Some of the initial contraindications to PEG are no longer considered even relative contraindications in some scenarios, because techniques have evolved that address the underlying concern; T-anchors can be used to aid in opposing the gastric and abdominal walls, and drainage and improved medical management of ascites allows safe PEG placement in some patients. These and other relative contraindications remain in Table 2 to provoke thoughtful planning as physicians consider PEG placement for complex patients. Specific technique modifications and management strategies will be highlighted in subsequent chapters of this text.

Table 2. Contraindications to PEG placement

Absolute	Relative
No opportunity for patient benefit	Limited opportunity for patient benefit
Diffuse peritonitis	Coagulopathy
Complete pharyngeal obstruction	Clinical instability, extremis, shock
Complete esophageal obstruction	Altered anatomy
Altered anatomy*	<i>Gastric resection, minor</i>
<i>Gastric bypass</i>	Regionalized peritonitis
<i>Gastric resection, major</i>	Ascites
Advanced dementia	Peritoneal dialysis
Lack of informed consent	Hiatus hernia
IV anesthetic contraindication**	Immunosuppression
	Head and neck malignancy
	Oral maxillofacial trauma
	High mortality patient group
	Inability to oppose gastric and abdominal wall
	<i>Despite use of T-fasteners, other techniques</i>
	Hepatomegaly
	Splenomegaly
	Portal hypertension with gastric varices
	Cirrhosis
	Conditions affecting the epigastric abdominal wall
	<i>Inflammatory, malignant, infiltrative disease,</i>
	<i>hernia, open wound</i>
	Obesity with extreme BMI > 60 kg/m ²
	Pregnancy

* May be a candidate for percutaneous endoscopic jejunostomy (PEJ) tube (see Chapters 10 and 14)

** May be a candidate for PEG under local/topical anesthesia only (see Chapter 5)

The patient with altered anatomy presents unique challenges in PEG placement. Partial gastrectomy may not preclude safe PEG placement, but more extensive gastric resection likely will make PEG impossible. Patients requiring feeding or decompressive access to the remnant stomach following Roux en Y gastric bypass generally are not candidates for PEG placement, although retrograde access to the remnant stomach using enteroscopy may be feasible in some circumstances [22]. In both of these circumstances, the endoscopist may have to consider placement of a percutaneous jejunal feeding tube (PEJ). Oral maxillofacial trauma treated with intermaxillary fixation has long been considered at least a relative contraindication to PEG because transoral gastric access is restricted by this therapy. Transnasal PEG placement, reported recently in this patient population, may provide feeding access for carefully selected patients [23-25]. When medically indicated, there is no age or weight limit that absolutely contraindicates PEG [2].

Assessing the impact that absolute and relative contraindications will have on PEG placement remains an important part of procedure planning. Physicians must continue to evaluate the needs and circumstances of patients in context with a critical evaluation of their own skill set and level of experience as they seek to provide solutions for patient needs.

DECISION MAKING

While PEG holds many advantages over other techniques, the decision for placement must be considered carefully on a case-by-case basis to assure that necessity, risk, and overall prognosis with and without enteral access are consistent with each patient's goals for their care and their likelihood for improvement [26, 27]. In many settings, PEG placement has become automated; a consult is placed by the primary care, internal medicine, hospitalist or trauma service and the procedure is scheduled after brief evaluation, primarily of procedure-related risk factors.

Table 3. Predictive indices of increased 30-day mortality following PEG

Patient clinical factors
Age > 75 years
ASA class IV
CCI > 4
BMI < 18.5 kg/m ²
Prolonged antibiotic needs
ASA – American Society of Anesthesiologists; CCI – Charlson Comorbidity Index; BMI – body mass index

Predictive modeling science has been applied to the decision-making process for PEG placement. Increased 30-day mortality rates after PEG long have been noted in patients with age >75 years, continued need for hospitalization after PEG, low serum albumin, persistent leukocytosis, chronic obstructive lung disease (COLD), diabetes, Glasgow coma score <10, advanced American Society of Anesthesiologists (ASA) risk score, Charlson Comorbidity

Index (CCI) >4, advanced malignancy, severe malnutrition, low albumin, and elevated C-reactive protein [28, 29]. Multivariate analysis demonstrates that age >75 years, ASA class IV, CCI > 4, BMI < 18.5 kg/m², and prolonged antibiotic needs predict increased 30-day mortality after PEG [30]. Patients with these factors should be evaluated carefully for PEG and their mortality risk realistically assessed prior to placement (Table 3). Acute and chronic PEG related complications are discussed in more detail in Chapters 17 and 18.

Figure 1. Decision algorithms for PEG placement in neurodegenerative or malignant disease states.

In order to support appropriate decision-making, an algorithmic approach to PEG is suggested (Figure 1) [27]. Patients with neurodegenerative disorders that are stable, or not rapidly progressing, typically benefit from PEG, whereas those in persistent vegetative states and those with end-stage dementia are not considered candidates for PEG because of their overall poor prognosis [21]. Cancer patients with dysphagia, aspiration, malnutrition, and other reversible factors, with reasonable risk profiles, anticipated survival greater than 30 – 60 days, and an opportunity for remission or cure, make excellent candidates for PEG when indicated for nutritional support [31, 32]. Those with diminished anticipated survival, or tumors that are or have become non-responsive to therapy generally are not considered suitable candidates for PEG. Finally, cancer patients with an obstructed gastrointestinal tract who are not suitable candidates for surgical remedy or in whom GI stenting has failed or is not possible may benefit from decompressive PEG [27].

INFORMED CONSENT

Despite its relative ease in scheduling and placement, the decision to proceed with PEG requires significant consideration and discussion with all involved parties and must take into account patient, family, guardian, and caregiver wishes, goals, expectations, and advance directives in order to establish a cohesive treatment plan. Although much of the discussion in the surgical care of patients involves an assessment of risk and development of risk mitigation strategies, PEG introduces considerations far in excess of those routinely considered in anticipation of an equivalently minor procedure. The risks are high with significant mortality rates associated with PEG at 30 days and 12 months. This life extending therapy, often provided in the wake of significant life-altering occurrences, might be inconsistent with patient wishes and desires. Given that the patient often has sustained a degenerative neurological event, stroke, or trauma, they may not be able to contribute meaningfully to the discussion or express their viewpoint adequately.

Patient autonomy and self-determination both are important doctrines central to the granting of informed consent for medical treatments and procedures. Patients have a right to make life choices, and are entitled to receive health care free of control by others, including family, staff, and providers. Patients are entitled to determine which recommended treatments and procedures they will avail themselves of without retribution, and without decisions being made by others that override their own. For patients to make these choices, they must be informed of facts and likelihoods related to treatments, procedures, and the refusal of treatments and procedures. The consent discussion for PEG often is a proxy for a more detailed discussion involving end of life issues that may or may not have been considered previously by the patient and their network. Robust palliative care support is an essential ingredient to efficient and appropriate use of PEG. Chapter 3 discusses the nuances in a more complete fashion.

Although it is well accepted that informed consent requires patient autonomy, in the case of determining acceptance of PEG, the patient may be all but autonomous, and there may be little or no indication of their pre-conceived decisions or thoughts relating to enteral access. Furthermore, there might be strong dispute among family members about what their relative would choose if they were capable of making that choice independently. PEG placement may

invoke the need for Ethics Committee consultation, and might strain family members and caregivers, all interested in protecting the patient despite their often polarizing views.

CONCLUSION

The introduction of percutaneous endoscopic gastrostomy revolutionized patient care, and for many years, PEG has provided a means of minimally invasive nutritional support for patients with a functional GI tract, and a means of decompression for patients with obstruction not amenable to stenting or surgery. Although the indications for PEG had been expanded over the decades following its introduction, including use in patients with dementia and those in persistent vegetative states, current thinking has evolved. PEG should be considered in patients with benign and malignant conditions in whom clinical improvement or stabilization is likely, and counseling against this invasive measure should be advocated for those with limited life expectancy and little chance for improvement, or at high risk for early procedure-related mortality. An algorithmic approach to decision-making is advocated, although the most important determinant in PEG placement is a holistic approach to patient evaluation and care, one that takes into account clinical needs, risks, and social factors.

EDITOR'S COMMENT

The speed and relative simplicity with which PEG can be accomplished frequently hides the complex decision making processes that happen behind the scenes when a request for an endoscopic gastrostomy is placed. There are increasingly fewer absolute contraindications to PEG placement, but the absence of a contraindication does not imply that the procedure should be performed. As the authors point out, the risk benefit ratio for each patient (as well as the endoscopists comfort level with relative contraindications) needs to be examined for each patient in each circumstance. (EMP)

Chapter 124

PALLIATIVE CONSIDERATIONS OF GASTROSTOMY

Julie L. Mitchell, DO and Susan A. Glod*, MD

Penn State Hershey Medical Center, Hershey, PA, US

INTRODUCTION

Palliative Care is a rapidly-growing and increasingly available medical subspecialty that focuses on maximizing quality of life for patients with serious illness, regardless of the stage of illness and current treatment plan [1, 2]. Specialty Palliative Care provides management of complex or refractory symptoms, including pain, nausea, dyspnea, and anxiety, as well as assistance in establishing goals of care in the setting of complex illness, and managing challenging communication [3]. Timely consultation has been shown to improve quality of life and decrease healthcare costs, and in some instances has been associated with lengthened lifespan [4, 5, 6]. As population needs outstrip the supply of available specialists, and in order to avoid the unintentional undermining of existing relationships between patients and current providers, the role of the Palliative Care consultant has become increasingly more well-defined [3].

It should be noted that for a variety of reasons, including the relatively short life expectancy of patients who are seen by palliative care specialists, ethical challenges in enrolling members of this vulnerable patient population, and difficulties with trial design inherent to studies that test the efficacy of what are often directions of care rather than specific interventions, there are relatively few published randomized prospective clinical trials within the palliative care literature in comparison to other specialties [7]. This landscape is changing as the evidence base of high-quality, specialty-specific literature expands, but current published randomized studies to address the use of gastrostomy tubes are still a rarity. But despite this lack of data, it is likely that discussions around procedurally-based interventions, including gastrostomy tube placement, will occur between the patient and the proceduralist. This chapter will review the available literature and make recommendations about the palliative considerations of gastrostomy tube placement.

GENERAL CONSIDERATIONS

The minimally invasive nature of percutaneous endoscopic gastrostomy (PEG) makes it a viable consideration in patients with life-threatening progressive illness [8]. The two populations of patients in whom this therapy is most utilized for palliation include those with progressive neurologic disorders, such as amyotrophic lateral sclerosis (ALS) and Parkinson disease, and those with malignancy, often of the gastrointestinal tract or oropharynx. Gastrostomy is most commonly used as a means to establish enteral access for feeding and to enable GI decompression [8]. Weight loss, decreasing BMI, and deteriorating nutritional status as a result of nausea, vomiting, or dysphagia secondary to the underlying disease process are considerations when determining the appropriateness of PEG placement in these patients [8]. Although medication administration alone is usually not a sufficient cause for PEG insertion, this can play a role in decision-making, particularly when medications needed for symptom management are not available for administration through buccal, rectal, or transdermal routes.

Each individual patient's goals and values should be taken into account when considering PEG placement. A provider should consider end-of-life decision making and lead a basic discussion of harm versus benefit analysis when making decisions regarding PEG insertion in these patients [8]. Careful discussion of and agreement upon the expected goals of placement, (e.g., medication administration, relief of nausea or abdominal distention through venting, etc.) versus the limitations (e.g., whether or not patients should expect improvement in weight or functional status when PEG is placed in the setting of advanced malignancy) and potential burdens (e.g., procedural complications, dislodgement, abdominal symptoms related to enteral nutrition) should occur and be documented in the medical record. In this patient population, ongoing discussions of goals of care are vital, and careful documentation of the goals of gastrostomy placement can provide a basis for future providers to continue this discussion. In a review of 154 consecutive adults undergoing PEG for palliative purposes, only one medical record documented a procedure-specific discussion of benefits and burdens and alternatives to tube feeding [8].

CONSIDERATIONS PRIOR TO PLACEMENT

If PEG placement is for the purposes of hydration or nutritional support, the reason(s) behind the patient's dehydration and/or malnutrition should be considered. As a general rule of thumb, patients who are experiencing hunger but are unable to eat because of anatomic or neurologic reasons are most likely to benefit from placement. If patients do not have a physiologic barrier that prevents oral intake, but they either do not have a desire to eat or are experiencing decreased consciousness as a result of disease progression, they may gain less benefit from enteral nutrition.

From a legal and ethical standpoint, artificial nutrition is no different from any other life-sustaining therapy, such as antibiotics, hemodialysis, or ventilatory support [8]. That having been said, the decision to withhold or withdraw artificial nutrition and/or hydration can be incredibly emotionally charged for patients, their caregivers, and clinicians as well. Decisions to withhold or withdraw nutrition, and thus often decisions to pursue gastrostomy, must take

into account a patient's individual cultural and spiritual beliefs as well as goals of care. Patients and families may often express concerns that by not pursuing artificial nutrition they are hastening death through starvation. In addition to empathic listening and emotional support, general discussion points under these circumstances may include the following: in the absence of hunger, patients do not experience the symptoms typically associated with starvation; artificial nutrition in the terminal stages of illness can be associated with an increased symptom burden; artificial nutrition in the last stages of terminal illness does not prolong life and may in fact confer an increased risk of mortality (see below).

If there is uncertainty as to whether a patient will benefit from PEG placement, a trial period of enteral feeding and/or hydration through nasogastric or nasojejunal feeding may be helpful in clarifying expected outcomes. Similarly, if the tube is to be used for decompression, a trial of nasogastric decompression is helpful in clarifying the degree of symptom (e.g., nausea, abdominal pain) relief. Prior to insertion, patients, families, and clinicians should agree on a set goal (for example, improved delirium, improved functional status, time for rehabilitation to improve swallowing ability) as well as a reasonable time period over which these improvements can be expected. We suggest a period of 2-4 weeks. A plan of care in the event that the agreed-upon goal is not met after the trial period, or if patients experience increased symptom burden related to artificial nutrition, such as worsening anasarca, pulmonary edema, or ascites, should be established prior to initiation of artificial nutrition. No ethical or legal distinction exists between withdrawing artificial nutrition and choosing not to initiate it in the first place, and this consideration should not impact decision-making.

POPULATIONS FOR WHICH PEG MAY NOT BE BENEFICIAL

Patients in the Last Days to Weeks of Life

Adequate nutritional support is a well-accepted facet of supportive care in patients with good functional status, regardless of disease type. Cachexia, which includes decreased appetite, weight loss, diminished functional status, and sarcopenia, is a common condition in many terminal illnesses, and is often a predictor of limited prognosis [9-12]. Data to support the use of enteral nutrition in patients with relatively good functional status but an anticipated life expectancy in the range of several months is mixed. An individualized choice, after discussion of the potential benefits as well as potential burdens (disruption to activities of living, caregiver fatigue, and complications associated with line/device placement) is warranted [13].

For patients in the last days to weeks of life, no compelling evidence for improvement in symptom control or quality of life with artificial nutrition has been demonstrated [13, 14]. Early evidence suggested that dying patients with poor oral intake and delirium may experience improvement in mental status with hydration, but this has not been demonstrated in subsequent studies [15, 16].

Patients with Advanced Dementia

Patients with advanced dementia may experience prolonged periods of diminished functional status, including decreased oral intake and difficulty swallowing prior to death. This is often complicated by weight loss, malnutrition, decubitus ulcers, and recurrent episodes of aspiration [17, 18]. A 2009 Cochrane Review found no benefit of artificial nutrition on survival, risk of aspiration, development or healing of decubitus ulcers, or functional status in patients with advanced dementia [19]. Furthermore, mounting evidence suggests that alternative means of nutritional support may be detrimental to this population, as evidenced by an observational trial that demonstrated higher mortality rates in patients after initiation of alternative means of nutritional support versus patients who were provided with oral feeding alone [20].

It is important that discussions around nutrition in patients with advanced dementia or other neurodegenerative diseases are not limited to binary options of artificial nutrition versus no feeding. An individualized feeding plan, focused on the patient's comfort and usually managed through careful hand feeding and strategies to minimize aspiration, is appropriate in these circumstances [21]. In such cases, the goal of the intervention is not to obtain sufficient caloric intake, but to maintain social engagement, support cultural, ritual, and personal significance to patients, and to involve family members and other loved ones in the patient's care [22].

POPULATIONS FOR WHICH INSERTION SHOULD BE CONSIDERED

Proximal Obstruction – Head and Neck Cancers

Patients with proximal obstructing lesions may develop swallowing difficulties long before their malignancy impacts their functional status or other aspects of quality of life, making long-term enteral feeding an appropriate choice for this population. The most common indication for PEG insertion in patients with known or impending proximal obstruction remains long term enteral feeding for nutritional support in those who are unable to swallow or maintain sufficient oral intake [23, 24]. Patients who undergo gastrostomy under these circumstances experience improvement in nutritional status and quality of life [24]. PEG placement for nutritional gains may allow for more aggressive or effective disease-modifying therapy with enteral access for a finite period [24]. Though it does not impact long-term survival at 4 years, studies have shown that PEG allowed for better attainment of full-dose chemotherapeutic regimens by minimizing weight loss throughout therapy and improved short-term survival at 12 months [8]. The improvements in quality of life gained with PEG appear to outweigh survival benefits.

In this population, PEG placement is most beneficial intraoperatively or after tumor resection rather than preoperatively [25]. Patients who had PEG placed before resection of their proximal cancer had the highest complication rate of 57%, while those who underwent PEG intraoperatively or postoperatively had a much lower complication rate between 11% and 7% [8, 25]. The authors noted that intraoperative placement also conveyed the benefit of

minimizing anesthesia and operative time, and suggested intraoperative placement as being the safest and most efficient timing of PEG placement.

Neuromuscular Disease – ALS

Malnutrition is associated with reduced survival in ALS patients, as it contributes to muscle atrophy and diaphragmatic weakness [26]. The American Academy of Neurology (AAN) recommends gastrostomy placement for nutritional management when weight loss of more than 10% over baseline occurs and/or before functional vital capacity (FVC) falls below 50% of predicted [26]. Gastrostomy placement in patients who have ALS with dysphagia may confer a survival benefit of approximately six months [26]. Results of studies investigating the impact of FVC on the success of gastrostomy placement are mixed. In one trial, patients with mean FVC of 36% who underwent gastrostomy experienced a 30-day mortality rate of 9.6%, while those with FVC of >50% had a 30-day mortality of 0%, suggesting that the timing of insertion may impact survival. Gastrostomy placement prior to the development of respiratory insufficiency may be most effective [8, 26, 27]. Another trial demonstrated comparable mortality between patients with ALS and dysphagia with FVC above and below 50% [26]. More data is needed in order to establish the best timing for gastrostomy placement in this patient population.

Variables such as culture, site of onset of disease, and rate of disease progression may confound survival data. Patients with spinal-onset ALS receiving a PEG have been observed to have a significantly longer survival (8 months) than those who did not. For bulbar-onset patients, there was a 3 month survival advantage in favor of PEG placement, although here the difference was not significant [26]. Factors that may improve quality of life should be considered, as well. For example, the social interactive role of eating by mouth along with the PEG feedings for nutritional supplementation may improve quality of life, though is a largely understudied variable [26].

Gastric Outlet or Malignant Bowel Obstruction

A recently-proposed specific definition of malignant bowel obstruction by an international consensus group includes the following criteria: a) clinical evidence of bowel obstruction, b) obstruction distal to the ligament of Treitz, c) intra-abdominal primary cancer with incurable disease, or d) non-intra-abdominal primary cancer with clear intraperitoneal disease [28]. Symptoms of malignant obstruction may be secondary to mechanical impedance, motility dysfunction, aggregation of secretions, diminished intestinal absorption, and inflammation [29]. Refractory symptoms can lead to a significantly diminished quality of life, such as increased hospital admissions and poor oral intake [23]. Obstruction is common in advanced malignancies, most frequently colorectal, pancreatic, and gynecological cancers, with a global prevalence of occurrence in 3-15% of all individuals with cancer [23, 30]. Abdominal carcinomatosis, ascites, and gastric disease are frequent complications within this patient population, in whom prognosis is often poor and associated with considerable suffering [31].

Gastric outlet obstruction secondary to unresectable primary or metastatic malignancy complicates 20-30% of periampullary malignancies, leading to a variety of symptoms such as nausea, vomiting, abdominal pain, and dysphagia, often leading to oral restrictions [32]. Survival outcomes in patients with malignant gastric outlet obstruction are poor, therefore effective palliation of symptoms is an important goal [32]. While focal obstruction is often best managed by surgical bypass or endoscopic stenting, the risk of surgical intervention may outweigh the benefit in patients with very limited prognoses [29]. In this population, gastrostomy placement for symptom management through decompression may be a viable option [33].

Parameters for and Timing of Insertion for Decompression

Nasogastric (NG) decompression, along with hydration, electrolyte management, and the administration of analgesics and anti-emetics is often included in the initial management plan for malignant obstruction [23]. This allows for immediate symptom relief in most patients and affords time for patients and their loved ones to engage in discussions of goals of care. A patient's symptomatic response to nasogastric decompression can be used to help predict the effectiveness of PEG for symptom control through decompression. Seventy-three percent of patients who underwent gastrostomy had experienced good symptomatic response to NG decompression [23]. Ninety-three percent of those patients with documented improvement in their symptoms with an NG tube in place had no readmissions for obstructive symptoms after gastrostomy [23]. If relief is obtained from NG decompression, venting gastrostomy is a reasonable next step in order to allow for less nasogastric discomfort and minimize cosmetic factors associated with NG drainage [31].

The best timing for conversion of NG decompression to gastrostomy has not been established, and no formal guidelines for gastrostomy placement for symptomatic gastrointestinal obstruction are in place [23]. This is an important clinical decision, as up to one-third of patients with inoperable obstruction will experience spontaneous resolution with conservative management [30]. In a meta-analysis of the use of corticosteroids in malignant obstruction, a trend towards improved rates of resolution was observed with the addition of intravenous dexamethasone [34]. It is reasonable to suppose, then, that very early gastrostomy placement in patients who are undergoing active medical management for obstruction may place a subset of patients at unnecessary procedural risk. More than half of these patients, however, will experience recurrence of the obstruction [30]. If it is felt that the patient is at high risk for recurrence, and if gastrostomy for symptom management is consistent with the patient's overall goals, we typically recommend gastrostomy placement for venting in the future, lest the patient be too debilitated at the time of recurrence to tolerate the procedure.

Functional Outcomes of Decompressive PEG

The presence of a malignant bowel obstruction is in-and-of itself a poor prognostic indicator, and prolonged survival is usually a secondary consideration after effective management of symptoms. Functional status at the time the obstruction occurs tends to be most predictive of survival in this population; in one study the most significant factor related

to the patient's survival was his or her Eastern Cooperative Oncology Group (ECOG) status prior to gastrostomy [31]. Even in patients with poor performance status, gastrostomy can provide substantial relief; therefore limited functionality should not preclude gastrostomy but should be factored into continued discussion with patients and families regarding decision-making and goal setting [31]. Patients with poor performance status, rapidly progressive disease, carcinomatosis, malignant ascites, very short (<30 days) life expectancy, or failure of previous surgical intervention or stenting are often best served by observation or palliative gastrostomy rather than other surgical interventions [32].

Complete relief of obstructive symptoms was found in a high proportion of patients (84-97% in multiple studies [23, 29, 31, 33, 35]. Resolution of symptoms occurred quickly, with a mean number of days to relief of 1.7 [31, 33]. Only 8% of patients were considered treatment failures due to continued symptoms with functioning PEG in place [23].

Following decompressive PEG, many patients are able to resume oral intake of fluids and softer foods [31]. There is a large range of oral tolerability after PEG, from sips to full meals, primarily dependent upon the patient's disease process [29]. Sometimes oral intake is still limited due to the location of obstruction, though overall, intake improved from pre-PEG diet [29]. Patients should be instructed on proper techniques for clamping and draining the gastrostomy. Symptom relief with the resolution of nausea and vomiting and the ability to take in soft foods and liquids within 7 days of the procedure was observed in 84% to 91% of patients [8, 35]. In one study, after an initial period of rest, patients were able to have liquids or pureed solids with the drainage tube to gravity with complete resolution of their symptoms (nausea and vomiting) in 91% of patients [33]. Eating for social interaction rather than nutritive benefits significantly improves quality of life, as well [31]. It has been our experience that after a few days, many individuals are able to self-regulate a schedule for venting the gastrostomy that results in good symptom control and minimizes disruptions to the patient's desired routine.

Improvements in quality of life are an important goal surrounding PEG placement. Although most hospice agencies are able to provide fairly intensive levels of home care, including nasogastric drainage if necessary, this can prove burdensome to patients and their loved ones. Gastrostomy placement may allow for the development of a pragmatic plan for palliation at home, thereby decreasing hospital readmissions and time spent in the hospital, for patients and families who otherwise may have been overwhelmed with the symptom burden associated with bowel obstruction [23]. PEG dysfunction requiring readmission for symptoms is infrequent, and in all cases of readmission due to PEG dysfunction, PEG was successfully replaced [23]. The average length of time spent at home prior to readmission for in-hospital palliation after PEG placement was 126 days, and these readmissions were not necessarily related to symptoms that would have been relieved by PEG [29]. Even at the end of life, gastrostomy can be successfully managed either at home or in an inpatient hospice setting, rather than in the hospital [33]. In one study of patients with gynecologic malignancy who had undergone gastrostomy, all patients died at home without recurrent symptoms of bowel obstruction with only very minimal abdominal symptoms up to 210 days [35].

Complications of Decompressive PEG

PEG placement is highly effective, not technically difficult, and is accompanied by a low complication rate [35]. Reported complications of palliative PEG are low, with an incidence of minor complications around 5% to 13% [8]. These include pain at the insertion site, skin excoriation, leakage of ascites and gastric contents, peristomal infections, skin excoriation, ileus, PEG tube migration, and tube blockage [31, 33]. Major complications, defined as those often requiring repeat endoscopic procedures, occur in only 1.3% to 3% of cases, and include peritonitis, inadvertent removal of the tube, fasciitis, and tumor implantation at the PEG site [8]. Infectious complications are higher in those with ascites, though this was decreased when ascites was drained prior to insertion of the PEG [23].

Overall, the morbidity rate related to PEG placement for decompression is only slightly higher than the same technique used for nutritional purposes [8]. Overall mortality is low at 0.2% to 1%. The median overall survival was worse in those who underwent initial palliation with PEG versus those who underwent endoscopic stent placement or surgical bypass (median 49 days versus median 64 days, respectively), though the patients were not offered bypass or stenting as a therapeutic option, indicating very advanced disease and short life expectancy in itself [32]. In the advanced cancer population, multifocal obstruction and/or poor surgical candidacy makes these aforementioned interventions rarely viable [23]. Overall morbidity and mortality rates relate to the underlying disease process rather than the PEG itself, which does not seem to hasten the patient's demise. Advanced tumor stage was an independent predictor of 30-day mortality [24].

Patients with high illness severity are more likely to have complications and are at increased risk of mortality after PEG insertion, as previously discussed. In patients undergoing venting PEG for palliation however, the benefits of improved symptomatic control may outweigh the mortality risk, particularly given already shortened life expectancy post-PEG [24]. In general, we advocate for earlier gastrostomy placement in order to maximize time spent with good symptom control.

Decision-Making for Decompressive PEG

The most important factors in decision-making regarding palliative PEG placement were physician's recommendations and the desire to eat and drink normally [32]. Patient and family goals and values play a large role here, as they often do in discussions surrounding palliative interventions. Fears of surgery or anesthesia were not reported to influence decision making [32].

Technical Considerations to Decompressive PEG

An unsuccessful attempt to place a decompressive PEG usually occurs because of malignant ascites, multiple previous surgeries, or tumor involvement of the abdominal wall, as these preclude transillumination. Fluoroscopy, computed tomography and transcutaneous US can be used to localize the best site when transillumination is not possible (see Chapter 13 for more information on the use of assistive techniques for PEG placement). Ascites and

abdominal carcinomatosis are not absolute contraindications to palliative PEG placement, though may make the procedure technically more difficult [23]. Ascites should be drained as much as possible before the procedure, which improves ability to transilluminate and decreases infectious complications [23]. A peritoneal catheter can be left in place for several days to allow healing at the gastrostomy site. Although hyperthermic intraperitoneal chemotherapy with attempted cytoreduction has been shown to be effective in management of malignant ascites, recovery time from this procedure can be as long as six months, making concomitant therapy for bowel obstruction and ascites less feasible [36]. Adding a gastropexy to the procedure may help to promote maturation of the tract and prevent leakage after PEG placement in patients that have ascites (see Chapter 9 for a discussion of gastropexy technique).

PEG placement is feasible even in patients with tumor encasing the stomach, diffuse carcinomatosis, and ascites [33]. These patients still quickly obtain significant symptomatic relief. When decompression with NG does not relieve symptoms, however, it is possible that patients will not respond well to PEG for decompression.

There is no standardized technique for insertion of palliative PEG. Only very minor modifications to the technique used for PEG insertion for nutritional purposes are required to adapt the technique to a wide variety of palliative indications. “Pull” method was used in most cases with good results [23, 24]. In most studies, tube size was not standardized [23]. One study showed that increased tube size did not reduce incident of tube blockage [29]. In one study, majority of patients had a 28 Fr tube with good results; however, prior studies have shown that 15-20 Fr tubes are large enough to provide adequate decompression [33]. Another recommends 20 Fr tube in comparison to 15 Fr, as it has good decompressive effects, causes minimal abdominal wound, and allows introduction of smaller jejunostomy tube if necessary for better air decompression [35].

Medical Management

Medical management is the cornerstone of treatment for malignant bowel obstruction and pharmacologic intervention should be continued along with venting PEG [31]. For patients who do have recurrent nausea and vomiting despite PEG, octreotide has been shown to help symptoms by decreasing GI secretions and bowel distention [35].

Quality of Life Outcomes Following PEG

Studies evaluating overall quality of life (QOL) after PEG placement are significantly disparate [8]. The severity of the underlying disease may preclude significant improvements in QOL, so this must not be the sole reason for PEG insertion. One study showed no significant improvement in any measure of QOL including functional status, cancer-related symptoms, or gastric-specific symptoms after PEG [32]. Another study showed similar results, though one third of this population included dementia patients [8]. Improvements in QOL are more likely to be observed when PEG is inserted for patients who have neurological disease or abnormalities in the GI tract than for those with dementia.

The perception of improved QOL for patients with palliative PEG seems to be different among caregivers and patients themselves. Improvements in QOL of family members of those receiving PEG have been evaluated. In one study, only 55% of patients said their QOL improved with PEG, while 80% of their family members reported improvements in their own QOL [8]. Another similar study showed no change in overall quality of life for patients, but 68% of their relatives reported that the patient's quality of life had improved [8]. Some of this disparity may be explained by differing expectations between families, caregivers, and clinicians after gastrostomy placement. Aside from relief of symptoms associated from the gastrostomy, patients are unlikely to feel better since nutritional parameters are not affected. Loved ones, on the other hand, may witness increased oral intake and interpret this as improved nutrition and QOL. Particularly in the setting of malignant obstruction, a frank discussion with patients and families outlining the anatomic role of the gastrostomy, and the high likelihood that despite increased oral intake, overall nutritional parameters are unlikely to improve, should take place prior to placement.

Supplemental Information

The Center to Advance Palliative Care website (www.getpalliativecare.org) provides general information on Palliative Care for patients, caregivers, and clinicians as well as links to sites dedicated to disease-specific management and support. The American Academy of Hospice and Palliative Medicine site, (www.palliativedoctors.org) provides answers to frequently asked questions about both palliative care and hospice as well as a description of palliative care services for patients.

EDITOR'S COMMENT

Appropriate patient selection for enteral access can be challenging as it is difficult to predict life expectancy in many of the patients that we are asked to place PEGs. This chapter succinctly describes the important issues that must be addressed in patients undergoing palliative PEG placement. Family involvement as well as careful assessment of underlying co-morbid diseases will allow the safest approach to this complex end of life issue. (JMM)

Chapter 125

PREOPERATIVE MANAGEMENT

Valerie Wu Chao Ying, MD and Jose M. Martinez*, MD

University of Miami, Miller School of Medicine, Miami, FL, US

INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) tube placement is a safe procedure that can be undertaken with minimal risks after adequate preoperative assessment. In addition to reviewing indications and contraindications of the procedure, potential complications can be reduced by taking specific steps such as ensuring appropriate antimicrobial coverage, managing antithrombotic therapy, ordering preoperative laboratory tests and imaging when necessary, as well as considering the needs of special populations such as those with implantable cardiac devices and on chemotherapy treatment. This chapter gives a brief overview and summarizes the latest evidence for each of these topics as well as our own personal approach.

ANTIBIOTIC PROPHYLAXIS

Patients undergoing PEG or percutaneous endoscopic jejunostomy (PEJ) tube placement are vulnerable to infections because of old age, compromised nutritional intake, immunosuppression, and underlying medical comorbidities, such as malignancy [1]. Peristomal infection represents one of the most common complications after PEG tube insertion with an incidence rate of 3 to 30% [2]. Infection involves the skin or subcutaneous tissue and typically presents with purulent discharge, erythema, tenderness, induration or warmth around the feeding tube insertion site. Positive bacterial culture site and systemic leukocytosis can also be present.

The use of broad-spectrum prophylactic antibiotics has been shown to be effective in decreasing peristomal infections following PEG tube placement. A 2013 Cochrane systematic review which included 12 trials, with a total of 1271 patients, comparing the use of antibiotics

* Corresponding Author's Email: jmartinez4@med.miami.edu.

vs. placebo, as well as different antibiotic regimens, showed a consistently beneficial effect for antibiotics (OR 0.36, 95% CI 0.26 to 0.50). The antibiotics selection included intravenous (IV) cephalosporins and penicillins. The timing of administration varied but mainly ranged from 30 minutes to immediately prior the procedure [3].

Rates of methicillin-resistant *Staphylococcus aureus* (MRSA) infections have been rising in many hospitals and concerns have been raised regarding high rates of MRSA peristomal wound colonization and subsequent increasing rates of MRSA PEG site infections [4]. A 2007 retrospective analysis by Thomas, demonstrated that screening for MRSA, subsequent decontamination and antibiotic prophylaxis statistically reduces peristomal MRSA infection rates [5].

In accordance to 2015 American Society of Gastrointestinal Endoscopy (ASGE) guidelines, we recommend the use of an appropriate IV antibiotic (such as weight based dosed cefazolin) 30 minutes prior to skin incision. In areas where MRSA is endemic, we recommend screening, decontamination and targeted antibiotic prophylaxis to reduce MRSA peristomal infection (e.g., IV vancomycin) [6]. This is in addition to standard surgical skin prep with chlorhexidine prior to skin incision. Chapter 17 reviews additional preventative measure to reduce the risk of wound infections associated with PEG placement.

ANTITHROMBOTIC THERAPY

While managing patients on antithrombotic therapy, one should balance the bleeding risk of the procedure with the thromboembolic event risk associated with interruption of the therapy. One must keep in mind the numerous types of current antithrombotic therapy, their half-life and mechanism of therapy as all these play a crucial role on appropriate interruption of management.

Figure 1. Post PEG bleeding. A) Endoscopic evaluation demonstrated blood in the body of the stomach and no active bleeding from the gastrostomy. B) Blood clot was found in the pre-pyloric region.

Assessing Risk for Bleeding

Elective endoscopic procedures can be divided into high risk and low risk bleeding procedures. Low risk procedures which are associated with a bleeding risk of <1%, include diagnostic EGD, colonoscopy and flexible sigmoidoscopy with or without biopsy, endoscopic

retrograde cholangiopancreatography (ERCP) without sphincterotomy, endoscopic ultrasound (EUS) without fine needle aspiration (FNA) and enteral stent deployment. Examples of high-risk procedures which have a >1% bleeding risk, include polypectomy, EMR, biliary sphincterotomy, EUS with FNA and pneumatic dilation. PEG placement is considered a higher risk procedure with an overall bleeding complication rate of 2.5% (Figure 1) [7, 8].

Assessing Risk for Thromboembolism

The American College of Chest Physicians (ACCP) published guidelines in 2012 for the perioperative management of antithrombotic therapy. In this article, they suggest a risk stratification model for perioperative thromboembolism risk. High-risk conditions are associated with >10% annual risk for thromboembolism and include patients with:

- 1) mechanical heart valve with a prosthetic valve in the mitral position; caged-ball or tilting disc aortic valve prosthesis; or a recent history stroke or TIA within 6 months;
- 2) atrial fibrillation with a “Congestive heart failure, Hypertension, Age, Diabetes, prior Stroke” (CHADs) score of 5 or 6; or with a recent history of stroke or TIA within 3 months;
- 3) recent venous thromboembolism (VTE) within 3 months or severe thrombophilia (protein C/S and antithrombin deficiency; antiphospholipid antibodies).

Moderate risk diseases are associated with a 5-10% annual risk of thrombotic events and low risk conditions have a <5% annual risk of thromboembolism [9].

Antithrombotic Management

In accordance to the most recent guidelines published by ACCP (2012) and ASGE (2016), we have summarized the periprocedural management of antithrombotic therapy [9, 10]. Of note, these guidelines are supported by few prospective randomized trials and are primarily based on observational studies, expert opinion and extrapolation from studies on other surgical procedures. These recommendations do not stem from studies specifically evaluating PEG tube placement.

Warfarin

For elective endoscopic procedures in patients on temporary anticoagulation therapy (e.g., deep venous thrombosis), we suggest delaying the procedure until anticoagulation is no longer needed if possible. In patients with a high thromboembolic risk, we recommend stopping vitamin K antagonist (VKA) such as warfarin, 5 days prior to PEG placement. In these patients, bridging anticoagulation is also recommended with either unfractionated heparin (UFH) or low molecular weight heparin (LMWH). In low risk patients, we suggest stopping and resuming VKA with no bridging anticoagulation. In moderate risk patients, individualized risk assessment is suggested. International normalizing ratio (INR) testing the day before surgery is also recommended to ensure timely identification of patients with

elevated INRs requiring additional reversal agents such as vitamin K (1.0-2.5mg). Warfarin can be restarted the same day as the procedure in all patients with adequate hemostasis.

Heparin

In patients receiving therapeutic dose of IV unfractionated heparin, we recommend stopping UFH 4 to 6 hours prior to the procedure. In patients receiving therapeutic dose of sub cutaneous (SC) LMWH, we suggest administrating the last dose of LMWH 24 hours prior to the procedure and resuming therapy 48 to 72 hours after.

Antiplatelet Therapy

There is limited data on the bleeding risk associated with the use of antiplatelet agents in patients undergoing PEG placement [11-16]. A recent systematic review of eleven studies with a total of 6,233 patients (among whom 3,665 were undergoing antiplatelet treatment) showed that antiplatelet therapy did not increase the risk of bleeding during PEG tube insertion. Pooled relative risk (RR) for bleeding in patients taking aspirin, when compared to controls, was 1.43 (95% CI 0.89, 2.29; I² = 0%); pooled RR for clopidogrel was 1.21 (95% CI 0.48, 3.04; I² = 0%) and for dual antiplatelet therapy, 2.13; (95% CI 0.77, 5.91; I² = 47%) [17].

The most recent ACCP guidelines suggest that aspirin should be continued in patients at moderate to high risk for cardiovascular events [9]. In patients with a coronary stent who are receiving dual antiplatelet therapy, they recommend deferring the procedure for at least 6 weeks after placement of a bare-metal stent and for at least 6 months after placement of a drug-eluting stent instead of proceeding with the procedure within these periods. If the procedure is deemed necessary during this time-frame, they recommend continuing the antiplatelet therapy perioperatively instead of stopping them. For procedures scheduled after these intervals, thienopyridine can be stopped 5-7 days before the PEG tube insertion and aspirin should be continued. Specifically, clopidogrel should be stopped 5 days prior to the procedure and prasugel 7 days prior to procedure. Both can be resumed once hemostasis has been achieved, usually within 24 hours, with or without an initial oral loading dose, depending on the anticipated risk of thrombosis and bleeding [9, 10, 16].

Novel Oral Anticoagulants

There is a paucity of data regarding the management of novel oral anticoagulants (NOAC), such as dabigatran, rivaroxaban and apixaban, in the elective endoscopy setting. The current guidelines reflect expert opinion and suggest that NOAC are held for 2-3 half-lives, which corresponds to 24-72 hours in patients with normal drug elimination. In patients with impaired kidney function, cessation duration needs to be adjusted accordingly. After hemostasis is secure, NOAC can typically be resumed 24-48 hours after the procedure. Of note, the peak plasma concentrations occur within 2 to 3 hours of the first dose, which differs from warfarin which full anticoagulation effect is achieved days after [10, 18].

In light of the complexity of antithrombotic management and the lack of strong randomized data, we recommend evaluation of each patient on a case-by-case basis in coordination with a cardiologist and/or hematologist. Tables 1 and 2 summarize the basic recommendations for the management of anticoagulation and antiplatelet agents in patients with cardiovascular risk undergoing PEG [10].

Table 1. Summary recommendations for the management of oral anticoagulation in patients with cardiovascular risk

Patient Cardiovascular Risk	
Low Risk	High Risk
1. Discontinue anticoagulation 2. Resume warfarin on the same day as the procedure 3. Delay resuming NOAC until hemostasis has been achieved	1. Discontinue anticoagulation 2. Bridge with UFH or LMWH 3. Resume warfarin on the same day as the procedure 4. Delay resuming NOAC until hemostasis has been achieved
NOAC – novel oral anticoagulants; UFH – unfractionated heparin; LMWH – low molecular weight heparin	

Table 2. Summary recommendations for the management of oral antiplatelet agents in patients with cardiovascular risk

Patient Cardiovascular Risk	
Low Risk	High Risk
1. Continue standard dose of ASA or NSAID 2. Discontinue thienopyridines* 5 days before or switch to ASA 3. If on dual therapy: stop the thienopyridine 5 days before, continue ASA	1. Continue standard dose of ASA or NSAID 2. Discontinue thienopyridines* 5 days before or switch to ASA 3. If on dual therapy: stop the thienopyridine 5 days before, continue ASA
ASA – aspirin; NSAID – nonsteroidal anti-inflammatory drug * thienopyridines include: clopidogrel (Plavix), ticlopidine (Ticlid), prasugrel (Effient) and ticagrelor (Brillinta)	

LABORATORY TESTING

Routine laboratory testing before PEG placement is generally not indicated [19]. Rather, pre-endoscopy laboratory tests should be performed selectively guided by history, physical examination, and patient's risk factors [20]. With that being said, patients undergoing PEG placement often have some degree of malnutrition and other risk factors, and it is reasonable to obtain a complete blood count, as well as an INR and aPTT preoperatively [21].

Figure 2. Patient with dysphagia secondary to amyotrophic lateral sclerosis who was initially refused a PEG based on A) CT scan demonstrating transverse colon (arrowheads) to be interposed between the stomach (*) and the anterior abdominal wall. B) Endoscopic findings were favorable for the placement of a PEG and fluoroscopic images showed inferior displacement of the colon (arrowheads) with gastric insufflation. A PEG was subsequently placed.

IMAGING

Routine imaging before PEG placement is not indicated. In certain scenarios, further delineation of the patient's anatomy may warrant additional imaging such as an abdominal computed tomography (CT) scan or upper GI series. Prior relevant surgery such as foregut surgery, bariatric, colectomy or abdominal wall hernia repair with mesh placement are likely to increase complexity of PEG placement and pre-procedure imaging should be considered in these populations. As discussed in Chapter 14, for example, CT scan can elucidate complex bariatric anatomy (such as the anatomical location of the alimentary limb following Roux-en-Y gastric bypass) to provide information about the ability to safely perform a direct percutaneous endoscopic jejunostomy tube. Known significant anatomical variants such as large hiatal hernia, or medical conditions such as ascites and hepatosplenomegaly may also alter the feasibility or the approach to the procedure and should be further investigated [21].

Even in cases where radiologic investigation may demonstrate non-favorable anatomy, we often proceed with upper endoscopy to evaluate feasibility of PEG as demonstrated by good one-to-one finger indentation motion, transillumination and safe-tract technique (Figure 2). In cases where imaging appeared non-favorable but endoscopic techniques proves favorable, we will proceed with placement of the gastrostomy tube.

IMPLANTABLE CARDIAC DEVICES

Patients with implanted electronic devices undergoing PEG placement should undergo the same precautions as when undertaking other endoscopic procedures. Electromagnetic interference may result from the use of electrocautery, causing inadvertent inhibition or triggering of cardiac devices. In 2007, ASGE published guidelines for patients with implanted cardiac devices undergoing endoscopic procedures, which can be summarize as follows:

- 1) Determine the type of cardiac device, indication and underlying patient's cardiac rhythm. This may be done in conjunction with the patient cardiologist or heart rhythm specialist.
- 2) Continually monitor the patient's cardiac rhythm throughout the procedure.
- 3) Have adequate resuscitation equipment available, in case the need for defibrillation or cardioversion arises.
- 4) Limit the use of electrosurgery, using the lowest effective power output for the shortest amount of time possible.

Most patients with cardiac pacemakers may undergo PEG placement including the use of electrocautery for hemostasis with no alterations in management. For patients with an implantable cardiac defibrillator (ICD) in whom the use of any electrosurgery is anticipated, it is recommended to have a consultation with the cardiologist or heart rhythm specialist ahead of the procedure to evaluate for the need of deactivation of the ICD function and reprogramming after the procedure with the help of a magnet [23]. Most PEG procedures do not require the use of electrosurgery. Minor bleeding can usually be controlled with temporary manual pressure, tightening of the bumper over the skin or by placing a suture.

IMMUNOSUPPRESSION

Endoscopic procedures in immunocompromised patients, particularly patients with severe neutropenia (absolute neutrophil count <500 cells/mL) and advanced hematologic malignancies carry a higher risk of bacteremia and sepsis [24]. Prophylactic antibiotics are recommended for these patients, as with any other patient undergoing PEG placement [10]. For patients undergoing active chemotherapy treatment, there are no specific guidelines regarding the management of chemotherapeutic agents before PEG tube placement. Certain agents, particularly those who impair angiogenesis by inhibiting vascular endothelial growth factor (e.g., bevacizumab) are known to affect wound healing and it is generally recommended that at least a month elapse between the last dose and major surgery [25]. A multidisciplinary approach to determine the risk and benefit ratio of continuing or stopping chemotherapy at time of procedure, or delaying the procedure until the systemic effects of these agents are minimized is recommended.

MALNUTRITION

Patients undergoing endoscopic feeding tube insertion often suffer from malnutrition, which also has been associated with an increased risk of complication after PEG placement [26, 27]. A retrospective review of 232 patients demonstrated that a low body mass index and advanced malignancies were poor predictors for complications [28]. As the patient's malnutrition worsens, the balance between the need for appropriate nutritional support compared to patient's increased post procedure morbidity must be carefully evaluated. To date, no clear guidelines are available to guide this decision making process.

EDITOR'S COMMENT

The preoperative management of a PEG patient is not to be underestimated. Bleeding after the procedure can be clinically significant and appropriate management of anticoagulation around the procedure is necessary. Similarly, the administration of antibiotics should be appropriately timed to reduce the risk of infection (See Chapter 17 for more details) which can be difficult to diagnose early in the PEG patient for a variety of reasons. Among these are the possible altered sensorium and inability to communicate symptoms related to infection. Doctors Wu Chao Ying and Martinez smartly note that unfavorable pre-operative imaging commonly does not equate to 'un-PEGable' and consideration should be given to an endoscopic evaluation prior to seeking alternative means of enteral access (EMP).

Chapter 126

ANESTHESIA FOR PEG TUBE PLACEMENT

S. William Hazard*, III, MD

Penn State Hershey Medical Center, Hershey, PA, US

INTRODUCTION

Patients present for PEG tube placement for a variety of anatomic or physiologic derangement ranging from neurologic diseases such as amyotrophic lateral sclerosis (ALS), traumatic brain injury (TBI) and stroke to aerodigestive dysfunction or surgical resection. As such, no single anesthetic protocol can meet the needs of all patients. The success of any anesthetic relies on a comprehensive assessment of each of the patient's comorbidities, careful patient preparation and a thorough understanding of the proceduralist's expectations. This is done in an attempt to minimize the risks associated with procedural analgesia and sedation. Guidelines from the American Society of Anesthesiology and the American College of Cardiology aid practitioners in achieving this goal. The purpose of this chapter is to provide recommendations for the pre-procedure evaluation of patients scheduled for a percutaneous endoscopic gastrostomy (PEG) tube placement. Anesthetic technique definitions (sedation, monitored anesthesia care (MAC), general anesthesia, or a combination of techniques), indications, commonly used anesthetic agents as well as immediate and long-term sequela of related to anesthesia will be discussed. This information aims to aid practitioner's decision making related to both the timing and anesthetic plan for this procedure.

CARDIAC RISK ASSESSMENT

Regardless of the specific indication for PEG placement a careful cardiopulmonary assessment should be performed. The most recent guidelines for the Perioperative Cardiovascular Evaluation and Management of Patients Undergoing Non-cardiac Surgery were published jointly by The American College of Cardiology and the American Heart

* Corresponding Author's Email: shazard@hmc.psu.edu.

Association in 2014. The focus of these guidelines is to provide tools to aid the clinician in assessing preoperative cardiac risk and to recommend the necessity, and timing of cardiovascular testing [1]. These guidelines begin with a description of cardiac risk factors including coronary artery and valvular heart disease, congestive heart failure, rhythm and conduction disturbances, pulmonary vascular disease, implantable electronic devices, and cardiomyopathy. Individual recommendations are beyond the scope of this chapter however, knowledge of the patients existing comorbidities will allow practitioners to utilize risk indices and calculators to help predict perioperative cardiac morbidity.

There are a number of validated risk-assessment tools including; the Revised (Lee) Cardiac Risk Index (RCRI), the American College of Surgeons National Surgical Quality Improvement Program (NSQIP) risk prediction calculator, the Gupta myocardial infarction/cardiac arrest (MICA), and the Bilimoria ACS surgical risk calculator. All are simple to use and readily available. The RCRI is particularly easy to use and has been validated many times over in the past 15 years [2]. It consists of six independent predictors of major cardiac complications: high risk surgery, history of ischemic heart disease, heart failure, cerebrovascular disease, diabetes (requiring insulin) and creatinine greater than 2 mg/dL. These risk factors are additive and are used to predict the rate of cardiac death, nonfatal myocardial infarction and cardiac arrest. The likelihood of a cardiac event occurring ranges from 0.4% (with no risk factors) to 5.4% (if three or more risk factors are present) [3]. According to the guidelines, if the patient is at “low risk” (less than 1%), no further testing is recommended prior to the procedure [4].

When approaching perioperative cardiac testing, one of the simplest and most reliable predictor of perioperative cardiac events is the patient’s functional capacity. The functional status of the patient can be determined simply by evaluating activities of daily living [5]. Functional capacity is most often reported as Metabolic EquivalentTs (METs): 1 MET - dressing one’s self, 4 METs- climbing a flight of stairs, 10 METs - swimming or running quickly. Perioperative cardiac risk is increased in patients unable to perform 4 metabolic equivalents [1]. In fact, a study published in 1999 examined self-reported exercise tolerance in an effort to predict in-hospital perioperative risk. The authors found that the likelihood of a serious complication was inversely related to the number of blocks that could be walked or flights of stairs that could be climbed [5].

CARDIAC EVALUATION

Supplemental preoperative testing can be helpful when indicated. Indiscriminate testing, however, can lead to procedural delays, unnecessary evaluations, and increased healthcare costs and potential morbidity. Observational studies have demonstrated that abnormal electrocardiogram (ECG) findings occur in 4.6 to 44.9% of asymptomatic patients [6-9]. These abnormal findings led to cancellation of surgery or changes in management in only 0.46-2.6% of cases [6, 10]. Preoperative ECG is recommended, however, for patients with known coronary heart disease, significant arrhythmia, cerebrovascular or peripheral arterial disease, and for patients with significant structural heart disease [11, 12]. A stipulation to this recommendation is that an ECG may not be necessary if the surgery is *low risk* (such as PEG tube placement) [1].

Preoperative transthoracic echocardiogram (TTE) has the potential to modify both patient management and timing of a procedure. An association between low ejection fraction and postoperative complications has been clearly demonstrated, however, screening asymptomatic patients can lead to resource overutilization and added expense [13]. Determining which patients should be screened was made more difficult by a study of 1000 patients undergoing vascular surgery (both open and endovascular) published in 2010. Of the patients screened, nearly 40% had asymptomatic left ventricular failure. The presence of LV failure doubled the risk of 30-day cardiovascular morbidity and quadrupled the risk of long-term mortality [14]. Despite these findings, the American Heart Association and American Society of Echocardiography states there is no benefit to *routine* TTE screening. There are, however, situations in which TTE can be helpful [15]. Patients with dyspnea of unknown origin or worsening dyspnea as well as those with previously documented LV dysfunction (not assessed within one year) should undergo testing [1].

CARDIAC RISK MANAGEMENT STRATEGY

Following a stepwise approach to perioperative cardiac risk assessment, patients with CAD and poor (<4 METs) or unknown functional capacity should undergo stress testing only if further testing will impact medical decision in their perioperative care [16, 17]. The proportion of abnormal findings during stress testing, in appropriately selected patients, was noted to be as high as 61.9% (variability between studies was high: 15.2-61.9%). These findings lead to additional invasive cardiac testing in almost 40 percent of these patients [18, 19]. Patients with an elevated risk of perioperative cardiac events and excellent functional capacity (>10 METs) or elevated risk and moderate to good functional capacity (>4 METs to 10 METs) should proceed to PEG without further exercise testing with cardiac imaging [1]. Similar to other perioperative cardiac tests, there is no utility in routine screening of low risk patients before a non-cardiac surgery.

Recent myocardial infarction (MI), defined as occurring within 6 months, is an independent risk factor for perioperative stroke and is associated with an 8-fold increase in mortality [20]. Postoperative MI rates decrease substantially the further out from a prior MI the patient is, if the procedure is non-cardiac (e.g., PEG) [21]. This risk changes if the patient undergoes coronary revascularization (coronary artery bypass grafting or percutaneous coronary interventions) [22]. Many percutaneous coronary interventions are accompanied with coronary stent placement. Elective non-cardiac surgery should not be performed within 30 days after placement of bare metal stents or 12 months after the placement of drug eluting stents due to the risk of stent thrombosis. This recommendation is specific to patients in which dual antiplatelet therapy (DAPT) will need to be discontinued perioperatively [23, 24]. As reviewed in Chapters 4 and 16, current guidelines permit the continuation of aspirin in high-risk patients (such as those who received a stent within the last 12 months) undergoing PEG. If a patient does not undergo a coronary intervention (stenting) following an MI, it is recommended waiting ≥ 60 days before performing non-cardiac surgery [1].

NON-CARDIAC TESTING

In observational studies of asymptomatic patients, routine hemoglobin testing was found to be abnormal in 0.5% to 65.4% of patients [9, 10]. These findings led to cancellation of procedures and changes in management in 2.4-28.6% of cases [25-27]. Routine screening of asymptomatic patients is not recommended however, patients with liver disease, a history of anemia, bleeding, or other hematologic disorders should be screened [10]. The majority of transfusions in the perioperative period are due to either preoperative anemia, blood loss, or the result of liberal transfusion thresholds [28].

Recent studies have raised concerns that red blood cell (RBC) transfusions may be associated with higher mortality, increased hospital length of stay, and a higher incidence of organ dysfunction. As such Patient Blood Management (PBM) programs have attempted to reduce unnecessary RBC transfusions [29-33]. These programs attempt to optimize preoperative hematopoiesis by first determining the etiology of the anemia and then treating the underlying cause and to transfuse only when absolutely necessary. The AABB (formerly the American Association of Blood Banks) endorses a restrictive transfusion strategy (7 to 8 g/dL) in stable, hospitalized patients [34].

Coagulation testing (e.g., platelet count, aPTT and PT), to predict bleeding risk, is commonly performed in patients even when there is no known risk factors or history of excessive bleeding [35, 36]. This occurs despite the fact that coagulation testing of unselected patients *has not* been demonstrated to have *any* significant positive predictive value for bleeding risk [37-39]. Prothrombin and and partial thromboplastin time screening has both high false positive and false negative rates that can lead to unnecessary surgical delays and more costly testing [40]. In 2008, the British Committee for Standards in Haematology concluded that no further coagulation testing is indicated if a patients bleeding history is negative [37].

Serum chemistries, including glucose, sodium, potassium, renal and liver function studies are often ordered indiscriminately or as a part of protocol. They should only be obtained as indicated by patients with comorbidities affecting the endocrine, renal, or hepatic systems or those taking certain medications (such as diuretics or alternative therapies) [10].

SEDATION/ANALGESIA/ANESTHESIA

An understanding of accepted definitions will help a practitioner ensure that the type and doses of medications will produce the desired effect and will be unlikely to place the patient at risk (cause airway obstruction or create a situation requiring hemodynamic support). In an effort to eliminate ambiguity surrounding procedural sedation, the American Society of Anesthesiologists (ASA) has created a series of position statements defining levels of sedation (minimal and deep sedation, monitored anesthesia care, and general anesthesia) along with the associated physiologic derangements that can be expect at each particular level¹.

¹ Continuum Of Depth Of Sedation: Definition Of General Anesthesia And Levels Of Sedation/Analgesia Approved by the ASA House of Delegates on October 13, 1999, and last amended on October 15, 2014 and accessed December 2015 www.asahq.org.

Minimal Sedation/Anxiolysis is defined as a drug-induced state in which the patient can respond normally to verbal commands. Although patients are typically cognitively impaired, it is important to note that airway reflexes remain intact and both pulmonary and cardiovascular function remains normal.

Moderate Sedation/Analgesia, also known as “Conscious Sedation,” retains the patient’s ability to respond purposefully, but not normally, to verbal commands. During conscious sedation, a patient will respond to verbal commands alone or accompanied by light tactile stimulation. Without intervention, the patient must be able to maintain a patent airway and ventilate spontaneously. Cardiovascular function is usually unaffected at this level of sedation.

Deep Sedation/Analgesia patients cannot be easily aroused but will respond purposefully following repeated or painful stimulation. The key difference between deep and conscious sedation is that patients may not be able to maintain either the patency of their airway or sustain adequate ventilation without assistance from the practitioner.

Monitored Anesthesia Care (“MAC”) is a term used to describe *a specific anesthesia service* in which an anesthesiologist has been requested to participate in the care of a patient undergoing a diagnostic or therapeutic procedure. It is not meant to describe a particular depth of sedation.* Monitored Anesthesia Care will often include the same medications used for moderate/deep sedation, however the provider must maintain the ability to convert to general anesthesia should the need arise. The provider must also be able to rescue a patient’s airway should the patient develop airway obstruction as a result of the medications administered.

General Anesthesia is defined as a state of medically induced loss of consciousness that renders a patient unarousable, even by painful stimulation. The ability of the patient to *independently* maintain ventilatory function is often impaired. Patients typically require assistance maintaining airway patency and in some cases may require mechanical ventilation. Also included in the definition is the possibility that cardiovascular performance may be altered by the medications administered.

MEDICATION ADMINISTRATION

Medications used for sedation and analgesia are titrated to effect and it is often not possible to predict how individual patients will respond to either the medications themselves or the stimuli of the procedure. The ASA recommends that practitioners, when attempting to provide a particular level of sedation², be able to treat the consequences of a patient entering a deeper level of sedation (i.e., hypoventilation, hypoxia and hypotension). If deep sedation is planned, the practitioner should be proficient in both airway management and advanced life support. Whenever propofol is being administered, the ASA recommends it be done so by *practitioners trained in the administration of general anesthesia* and that he or she not be *simultaneously* involved in performing the procedure itself due to the likelihood of respiratory and/or cardiovascular instability.

² Standards For Basic Anesthetic Monitoring (Approved by the ASA House of Delegates on October 21, 1986, last amended on October 20, 2010, and last affirmed on October 28, 2015 accessed December 2015 www.asahq.org).

PATIENT MONITORING DURING PEG

Because of the rapid changes in patient physiology during sedation/anesthesia, the ASA has made recommendation regarding the type of monitoring during procedural sedation. Recommendations are specific to monitoring under general anesthesia however; more invasive monitoring should be considered if patient's condition dictates even if minimal sedation is being utilized. For example, if a patient has severe pulmonary hypertension where hypercarbia may lead to elevated right heart pressures, an arterial line for sampling of arterial carbon-dioxide (CO₂) level and/or capnography may be warranted.

With any level of sedation during placement of a PEG tube, some combination of oxygenation, ventilation, circulation and temperature monitoring should be performed. Oxygenation can be assessed by means of a pulse oximetry. To date, pulse oximetry remains the most widely used monitor during procedural sedation [41] [42]. Although the value of pulse oximetry during sedation/anesthesia cannot be overstated it is an inadequate monitor of ventilation. Oxygen saturation (SpO₂) rarely demonstrates significant changes during deep sedation even with significant hypercarbia particularly when supplemental oxygen is being delivered. This was nicely illustrated in a study examining the ability of end tidal CO₂ monitoring (during procedural sedation with propofol) to decrease the incidence of hypoxic events. The authors found that hypoxia was more likely (42% vs 25%) in patients without capnography. Furthermore, capnography predicted all cases of hypoxia (SpO₂ less than 93%) before its onset. The median time from capnographic evidence of respiratory depression (end tidal CO₂ greater than 50 mm Hg, ETCO₂ change from baseline of 10%, or loss of the waveform) to hypoxia was 60 seconds (range 5 to 240 seconds). (43) In addition to pulse oximetry and expired carbon dioxide; continuous electrocardiogram (ECG), heart rate and non-invasive blood pressure should be measured at least every five minutes during the procedure.

SEDATIVES AND ANESTHETIC MEDICATIONS

A wide variety of hypnotic, sedative and opioid medications are used for procedural sedation and or general anesthesia.

Benzodiazepines

Benzodiazepines activate γ -aminobutyric acid A (GABA-A) receptors within the brain producing anxiolysis, amnesia, sedation, and hypnosis, but without analgesia [44]. The sedative effects of benzodiazepines can vary widely especially in extremes of ages. In children, paradoxical excitement occurs in up to 10-15% of patients whereas the elderly are more sensitive to their sedative and respiratory depressant effects [45, 46]. Respiratory and cardiovascular depression is more likely to occur in critically ill patients with preexisting respiratory or cardiovascular instability [47].

Midazolam is the most commonly used benzodiazepine for procedural sedation in endoscopy [48]. Adverse effects of benzodiazepine use extend beyond the cardiopulmonary

system. Some studies have reported a relationship between benzodiazepine use and the development of delirium [49, 50]. Numerous prospective studies have demonstrated that patients who develop delirium after either general anesthesia or sedation, have an increased risk of mortality. This risk is independent of preexisting comorbidities [51, 52]. The author recommends that caution should be used when administering benzodiazepines for sedation or anesthesia in critically ill or hospitalized patients due to differences in the outcomes of patients treated with benzodiazepine-based versus non-benzodiazepine sedation (i.e., Propofol or Dexmedetomidine). These studies included a meta-analysis demonstrating that benzodiazepine sedation is associated with an increased ICU length of stay as well as an increase in the duration of mechanical ventilation [53].

Opioids

Opioids bind to receptors distributed throughout the central (CNS) and peripheral nervous system. Respiratory depression occurs with all opioids in a dose-dependent manner (related to their potency). Opioids interact with respiratory centers in the medulla and pons; areas of the brain that regulate rhythmicity of breathing [54]. Opioids are frequently co-administered with other sedative drugs leading to additive effects on respiratory depression, increasing the risk of hypoventilation and apnea [55]. Synthetic opioids, particularly fentanyl, can cause chest wall rigidity. This occurs more commonly with large doses, with rapid administration, and with co-administration of other induction agents such as propofol [56]. Synthetic opioids decrease the release of endogenous catecholamines during stimulating procedures. Patients who are hypovolemic or dependent on high sympathetic tone (heart/liver failure) are predisposed to hypotension [57]. Morphine, uniquely, can cause venodilation as well as histamine release, compounding this problem [58].

Propofol

Propofol (2,6-di-isopropylphenol) is one of the most (if not the most) frequently used induction agent in the world [42]. The current formulation of propofol is insoluble in water. As a result, it is prepared in an emulsion of oil, glycerol, and lecithin. Propofol has no intrinsic analgesic properties and its sedative/amnestic effects are mediated by activating the GABA receptor system [42]. Propofol is rapidly cleared from the central compartment, undergoes hepatic metabolism, and cleared by the kidney. Since it is so rapidly redistributed, and has no active metabolites, propofol is particularly useful for procedural sedation [59]. Propofol's respiratory depressant effects include hypoventilation, upper airway obstruction, and apnea. As with other sedatives, these effects are exacerbated with the co-administration of other hypnotic-sedatives or opioids [41]. Propofol decreases mean arterial pressure through peripheral vasodilation and negative inotropic effects [60]. Due to the frequency of adverse respiratory and hemodynamic events with the use of propofol, practitioners should have the skill, medications and equipment immediately available to deal with these problems should they arise.

Ketamine

The mechanism of action of ketamine is thought to be the inhibition of N-methyl-D-aspartate (NMDA) receptors within the limbic and thalamic systems of the central nervous system. This inhibition creates what has been described as “dissociative anesthesia.” It is characterized by having an unresponsive, spontaneously ventilating patient with his or her eyes open demonstrating a low frequency nystagmic gaze. It is also accompanied with increased lacrimation and salivation. This lacrimation and salivation, in combination with ketamine’s tendency to produce an unpleasant emergence (which includes vivid dreams and hallucinations), has limited its use [42]. Ketamine is frequently administered with a benzodiazepine in an attempt to prevent the psychotropic effects. This relatively simple solution is not entirely effective in decreasing the incidence of the ketamine emergence phenomena [61]. Despite these untoward side effects, ketamine’s unique ability to preserve cardiovascular function and maintain respiratory mechanics makes it unique among induction agents. These characteristics make it useful in patients with cardiopulmonary instability requiring procedural sedation that would otherwise poorly tolerate the administration of other medications.

Dexmedetomidine

Dexmedetomidine is an alpha-2 (α_2) agonist similar to clonidine. It exhibits a much higher specificity for the α_2 versus the α_1 receptor. It works by activation of transmembrane α_2 adrenergic receptors within the CNS, which results in sedation, anxiolysis, and analgesia. It does so with minimal effect on respiratory function and as such, end-tidal CO_2 , oxygen saturation, and respiratory rate are maintained [62]. Adverse hemodynamic effects with dexmedetomidine include hypotension and bradycardia, which are both dose related. In one study of adult patients undergoing vascular surgery who were given dexmedetomidine, 27% experienced a mean arterial pressure ≤ 60 mmHg (or a 30% decrease from baseline) or heart rate ≤ 50 beats/minute [63]. Dexmedetomidine has been used for procedural sedation for upper endoscopy although much less so than the other agents described. In one prospective, randomized study, the use of dexmedetomidine was found to have a similar incidence of gagging, patient satisfaction, patient discomfort, anxiety scores, and recovery time compared to midazolam. Its use had, however, higher endoscopist satisfaction and fewer episodes of retching [64]. In another study, sixty patients were randomized to receive either a loading dose of dexmedetomidine followed by a maintenance infusion, or midazolam during upper endoscopy. The authors concluded that dexmedetomidine was as safe and effective as midazolam [65]. Dexmedetomidine has also been found to be useful for procedural sedation in patients with obstructive sleep apnea or pulmonary hypertension in which depression of respiratory function can rapidly lead to cardiopulmonary collapse.

Topical Pharyngeal Anesthesia

There are conflicting reports regarding the efficacy of the use of pharyngeal anesthesia to facilitate upper endoscopy. In one study the effects of topical lidocaine on the ability of

patients to tolerate upper endoscopy (as assessed by the endoscopist) was examined. The authors concluded there was significantly greater acceptance/tolerance in patients receiving topicalization of the pharynx [66]. A meta-analysis including 53 studies and 5 RCTs concluded that pharyngeal anesthesia with local anesthesia before upper endoscopy improved both the ease of endoscopy and patient tolerance [67]. This is in contrast to a randomized, double-blind, placebo-controlled trial in which propofol sedation alone was compared to propofol in combination with pharyngeal lidocaine in patients undergoing upper GI endoscopy. The authors concluded that topical pharyngeal anesthesia reduced the gag reflex in patients and did not influence patient satisfaction or ease of the procedure as determined by the endoscopist [68].

Choice of Anesthetic

A number of factors, outside of patient tolerance and comorbidities, play a role in the choice of anesthetic technique for PEG tube placement. Anticipated technical difficulty (and therefore length of the procedure), the possibility for conversion to a laparoscopic or open procedure, and procedures occurring simultaneously during PEG placement must be taken into consideration.

Where the procedure will be performed will also play a role in the choice of anesthetic: If the patient's hemodynamics or respiratory function were to change unexpectedly, is the procedure taking place in a location with access to all the equipment and or assistance needed? If the procedure will be performed under general anesthesia, will there be appropriate nursing staff to safely recover the patient?

A safe anesthetic not only seeks to minimize cardiovascular events, in a location with adequate support and equipment, but also to anticipate any number of complications that can result from sedation and anesthesia. For example, dysphagia is common following stroke with frequencies reported as high as 81% [69, 70]. Cerebral, cerebellar, or brain stem strokes all can impair swallowing physiology [71]. Delivering a safe anesthetic to patients who have recently suffered from a stroke is likely to involve endotracheal intubation due to high aspiration risk at baseline. Seemingly mild physiologic derangements can be the determining factor performing the procedure safely with sedation or general anesthesia with spontaneous ventilation versus general anesthesia with mechanical ventilation via an endotracheal tube.

Choosing an anesthetic for PEG tube placement can only be made after all patient factors, proceduralist's expectations, and environmental factors have been accounted for. Careful preparation will lead to better patient and proceduralist satisfaction and will ensure that management of the patient's pain and anxiety will occur in a safe and controlled manner.

EDITOR'S COMMENT

This chapter provides a comprehensive overview of the peri-procedural issues in terms of risk stratification, anesthetic selection, and post-procedural management. Even the most efficient and safely placed PEG can be easily affected by an anesthetic complication. With all endoscopic procedures, risks beyond the actual endoscopic therapy will exist and it is

imperative that the endoscopist is astutely aware of techniques to identify and manage these scenarios (JMM).

Chapter 127

DIAGNOSTIC ENDOSCOPY DURING PEG

***Susan M. Wetzel, MD, Mei Chris Huang, MD, PhD
and John D. Mellinger*, MD***

Southern Illinois Univeristy, Springfield, IL, US

INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) tube placement has done much to minimize the risk associated with surgically placed gastrostomy tubes by obviating the need for open operation and general anesthesia. In comparison to other modes of gastrostomy formation, including radiologically placed gastrostomy, PEG has the added advantage of providing simultaneous evaluation of the mucosal surface of the upper gastrointestinal (GI) tract. For this potential advantage to be realized, the practitioner of PEG must be familiar with common foregut pathologies and their management. This chapter reviews common esophageal, gastric and duodenal pathology that may be encountered during PEG tube placement, and will succinctly summarize their current management, and any impact on PEG placement.

BARRETT'S ESOPHAGUS

Barrett's esophagus is a recognized premalignant change of the esophagus from stratified squamous epithelium to columnar epithelium with intestinal metaplasia including gastric surface cells, goblet cells and absorptive cells [1]. It is found in 6-15% of patients with symptomatic gastroesophageal reflux disease (GERD) undergoing esophago-gastroduodenoscopy (EGD), and 4% of all patients undergoing EGD [2, 3]. Barrett's esophagus is known to arise in the setting of GERD; additional risk factors include male gender, white race, obesity and obstructive sleep apnea [4, 5]. It represents a risk factor for the development of esophageal adenocarcinoma.

* Corresponding Author's Email: jmellinger@siu.edu.

Figure 1. Barrett's esophagus. Note the irregular Z-line with islands of gastric epithelium interspersed with squamous esophageal mucosa.

Identification of Barrett's esophagus is often possible by visual inspection, characterized by salmon colored gastric-type mucosa arising from the gastric folds with extension into the distal esophagus (Figure 1) [6, 7]. Once identified, biopsies are required to confirm the diagnosis, histologically confirmed by the presence of intestinal goblet cells, and to assess for the degree of any associated dysplasia. It is suggested that biopsies be taken of all suspicious lesions as well as four quadrant random biopsies, which may show intestinal metaplasia even in the absence of visual endoscopic findings [8]. This allows the pathologist to distinguish between nondysplastic Barrett's esophagus, low-grade dysplasia and high-grade dysplasia. This classification has ramifications on further treatment and surveillance.

For nondysplastic Barrett's esophagus, the risk of esophageal adenocarcinoma is only 0.12% to 0.38% per year [9]. Although there has been increasing interest in endoscopic intervention in this population, the mainstay of treatment has been acid suppression with proton-pump inhibitors (PPIs) and serial endoscopic surveillance with biopsy [7]. Surveillance recommendations include EGD with biopsy at one year and follow-up every three years onward [9, 10]. It is felt that aggressive acid suppression with PPIs significantly reduces the risk of progression to dysplasia [11]. Anti-reflux surgery may also be considered in certain patients, and while regression of Barrett's changes may be observed after such interventions, several studies have shown no significant difference in progression of Barrett's esophagus or symptom management between surgical intervention and medical management [12-14].

Low-grade dysplasia is also most commonly treated with medical management and increased surveillance with EGD with biopsy at 6 months and every year thereafter as long as dysplasia is identified [7, 9, 10]. In high-grade dysplasia, the risk of progression to adenocarcinoma is 6% per year, therefore more aggressive therapy is often employed [15, 16]. Management options include intense surveillance with EGD with biopsy every three months, endoscopic management and surgery [7]. Endoscopic options include electrocoagulation, various forms of ablation such as laser ablation, radiofrequency ablation and cryoablation, and endoscopic mucosal resection [5]. Given the risk of associated occult

malignancy, reported as high as 35-41% in some series, some advocate for esophagectomy in those with high-grade dysplasia [17, 18]. One advantage of esophagectomy is the lack of need for further surveillance; however, mortalities rates range from 4.9%-12.1% with long-term complications that may affect quality of life for years to come [19]. Ablation of dysplasia and long-term reduction in malignant risk are well documented through the use of such techniques, and in particular, radiofrequency ablation in the recent literature [20]. Given the success of such treatments, some also advocate for treatment of patients with low grade dysplasia or even nondysplastic Barrett's with high risk profiles, such as long segment disease in obese males or those with a family history of esophageal adenocarcinoma [21, 22].

Although Barrett's esophagus is not a contraindication for PEG placement, it does necessitate placement of patients with prolonged life expectancy to be placed in a surveillance program.

HIATAL HERNIA

Hiatal hernias occur when non-esophageal contents prolapse into the thorax via the esophageal hiatus, most commonly the proximal stomach. There are four types of hiatal hernia: a type I, or sliding hernia, occurs when the gastroesophageal junction (GEJ) migrates cranially as a result of weakening of the phrenoesophageal ligament; a type II is a pure paraesophageal hernia where the GEJ remains in place and proximal stomach herniates through a weakness of the phrenoesophageal-esophageal membrane; a type III is a combination of one and two; and a type IV is characterized by the presence of abdominal organs other than stomach in the thorax. Type one hernias are the most common, followed by type three and type two, respectively [23, 24].

Figure 2. Large hiatal hernia viewed antegrade from the gastroesophageal junction. Narrowing of the lumen corresponds to location of esophageal hiatus of the diaphragm.

Hiatal hernias can be diagnosed both endoscopically and radiographically. Endoscopically, a hiatal hernia is identified as the presence of the Z-line more than 2 cm above the hiatus (Figure 2) [6, 24]. Recognition of the hiatus endoscopically can be facilitated

by watching for the diaphragmatic ‘pinch’ with inspiration (Figure 3). Radiographically, a hiatal hernia may be seen as a soft tissue mass on chest x-ray and confirmed with a contrast study, or may be seen on CT as the presence of stomach in the thorax [23].

Figure 3. Diaphragmatic ‘pinch’ seen below the squamocolumnar junction.

If discovered, an asymptomatic type I hiatal hernia requires no intervention. Reduction of the hernia and an antireflux procedure is indicated in those with GERD symptoms, particularly if the patient’s symptoms are not readily controlled with lifestyle modifications and pharmacologic therapy. Asymptomatic paraesophageal hernias may also be safely observed, as the rate of progression of symptoms appears to be approximately 14% per year [25, 26]. In patients with symptoms in association with paraesophageal component to their hiatal defect, it is recommended that they undergo surgical repair due to the risk of progression to severe symptoms requiring emergent surgery such as volvulus [23]. These recommendations must be weighed against the risk of surgery in an already high risk population in need of a PEG.

Paraesophageal hernias can complicate PEG placement due to the intrathoracic position of the stomach and inability to identify a portion of gastric lumen below the costal margin to allow placement of the PEG. With endoscopic reduction of the herniated stomach, PEG can sometimes be performed. If neither transillumination nor finger depression on the gastric lumen can be appreciated, alternative techniques including surgical or radiographic guidance may be required to obtain gastrostomy placement. Additionally, consideration should be given to the addition of a jejunal extension to the PEG or a direct percutaneous endoscopic jejunostomy (PEJ) if concern exists that the hiatal hernia could result in reflux and aspiration of gastric enteral nutrition.

ESOPHAGITIS AND GASTRITIS

Inflammation of the esophagus and/or stomach is one of the most common findings on routine EGD. There are many causes of upper gastrointestinal inflammation such as reflux,

nonsteroidal anti-inflammatory drugs (NSAIDs), physiologic stress, drugs and viruses being relatively common.

Reflux Esophagitis

Reflux esophagitis is characterized by mucosal edema and increased vascularity (Figure 4) [6]. Several classification systems have been published to aid in defining the severity of reflux esophagitis, the most popular of which is the Los Angeles classification system that relies on the degree of mucosal breaks as identified on EGD. Class A esophagitis is disease in which there are one or more mucosal breaks not longer than 5mm and does not extend between the tops of two mucosal folds; class B involves breaks greater than 5mm but still not extending between the tops of two mucosal folds; class C mucosal breaks are continuous between two or more mucosal folds but less than 75% of the esophageal circumference; and class D involves more than 75% of the luminal circumference [27, 28]. The degree of reflux may be further characterized by pH monitoring. Biopsies are not required in the setting of typical reflux esophagitis, but should be taken if the diagnosis is questioned, or if there is concern for associated Barrett's esophagus. The mainstay of treatment remains medical treatment with proton pump inhibitors (PPIs). For those that fail medical management, antireflux procedures may be performed, but the risks of surgery must again be placed in the context of patients with comorbidities and potentially limited lifespans. Without treatment, continued exposure to gastric acid can result in esophageal structures, the treatment of which is discussed later in this chapter.

Figure 4. Reflux esophagitis.

Eosinophilic Esophagitis

Eosinophilic esophagitis is a chronic immune-mediated entity often found in children, but also increasingly in the adult population, and occurs predominantly in males. It is characterized by mucosal edema, longitudinal furrows, mucosal fragility, whitish exudates, esophageal rings (also sometimes referred to as “trachealization”) and diffuse luminal

narrowing (Figure 5). It is felt to be caused largely by food allergens, but there appears to be a genetic component as well. Symptoms usually include dysphagia, food impaction and GERD like symptoms. Biopsy is required for diagnosis and it is recommended that biopsies be taken throughout the esophagus as at least three biopsies are required to confirm the diagnosis. On histology, at least 15 eosinophils per high-power field are consistent with the diagnosis of eosinophilic esophagitis in the appropriate clinical setting. Topical steroids and dietary modification represent the first line treatment, along with symptom management with esophageal dilation [29-32].

Figure 5. Eosinophilic esophagitis.

The presence of diffuse luminal narrowing may alter the method of PEG placement if the endoscopist has concerns about the ability to pull or push a gastrostomy tube through the diseased esophagus. In such cases, an introducer method of PEG may be considered.

NSAID Gastritis

NSAID-related gastric effects are present in 50-90% of patients after regular use. Findings include subepithelial hemorrhages, erosions and/or ulcers (Figure 6). These pathologic findings are thought to be caused by the inhibition of prostaglandin synthesis by this class of drugs, undermining their mucosal protective effects, as synthetic prostaglandins such as misoprostol have been found to reduce the incidence of NSAID induced damage. Treatment includes cessation of NSAID therapy, if possible, and the addition of a PPI or histamine 2 (H_2) antagonist [33, 34]. The endoscopist performing PEG should communicate these findings to the primary care team to ensure that proper therapy is administered.

Stress Gastritis

Stress related gastritis occurs in the vast majority, 75-100%, of critically ill patients when endoscopic examination is undertaken. This is typically seen as erosions and ulcerations that

begin in the proximal stomach and progress distally. Fortunately, clinically significant bleeding secondary to stress gastritis is uncommon, occurring with an incidence of approximately 3-4%. Stress gastritis is thought to occur when gastric defensive mechanisms such as mucous production, prostaglandin synthesis and mucosal blood flow are impaired by mucosal ischemia causing cell death and free radical production. Mechanical ventilation greater than 48 hours and coagulopathy are two well-recognized risk factors that predict the development of clinically significant bleeding. PPIs or H₂ antagonists should be used in the critically ill to prevent clinically significant bleeding, with the former showing greater clinical and cost effectiveness [35-39].

If the degree of gastritis is severe (most notably with the loss of mucosal integrity) postponement of PEG placement might be considered.

Figure 6. Distal gastritis related to NSAID use. Note the patchy erythema and mucosal edema.

VARICES

Esophageal and gastric varices are seen endoscopically as enlarged submucosal veins underlying normal mucosa within the distal esophagus and gastric cardia and fundus, respectively, of patients with cirrhosis and associated portal hypertension [6]. Varices have been found in 30% of compensated and 60% of decompensated cirrhotics at time of diagnosis [40]. They are known to have a hemorrhage rate of 5-15% per year [41]. In 10% of patients, isolated gastric varices can be caused by splenic vein thrombosis and associated isolated splenic compartment portal hypertension, usually secondary to pancreatitis or cancer. Varices develop as the portal pressure increases such that blood flow is redirected to lower pressure collateral systems such as the abdominal wall (resulting in *caput medusa*), the stomach and esophagus (resulting in varices) and the rectum (resulting in hemorrhoids) [42]. Features as seen on endoscopy that predict a higher incidence of hemorrhage include larger size, red wale signs (a longitudinal red streak on a varix suggestive of recent bleeding) and varix on varix. Non-endoscopic predictors include alcoholic origin of cirrhosis, Child class B or C, and a hepatic venous portal gradient of greater than 12mmHg [43, 44].

Esophageal Varices

Patients with esophageal varices usually present in two ways, either by routine screening after the diagnosis of cirrhosis has been made, or with acute hemorrhage. Once detected, it is recommended that measures be taken to prevent hemorrhage. In patients with no varices on initial endoscopy, surveillance should be performed every 2-3 years, while those with low-grade varices should have yearly surveillance. Primary prophylaxis consists of oral non-selective beta-blockers, such as propranolol, and regular endoscopic surveillance. Endoscopic rubber band ligation may also be used as primary prophylaxis in those found to have varices on surveillance endoscopy. Rubber band ligation is performed by placing rubber bands at the base of the varix causing thrombosis and mucosal necrosis. Repeat ligations are performed every 1-2 weeks until complete resolution is seen. In patients who present with gastrointestinal bleeding secondary to esophageal varices endoscopic methods such as rubber band ligation or injection sclerotherapy may be used to control bleeding. Once the hemorrhage has been controlled it is recommended that a non-selective beta-blocker be added to prevent future bleeding. Additional procedures such as transjugular intrahepatic portosystemic shunt (TIPS), in which a stent is placed from the portal vein to the hepatic vein by a radiologist to reduce portal vein pressure, or surgical shunting may be performed [45, 46].

Gastric Varices

Gastric varices are categorized into four separate entities based on their location by the Sarin classification [41, 47]. Gastroesophageal varices are esophageal varices that extend below the GEJ and onto the lesser curve of the stomach or onto the fundus, GOV1 and GOV2 respectively. Isolated gastric varices can occur on the fundus or sporadically throughout the stomach (IVG1 and IVG2). Although hemorrhage from isolated gastric varices occurs less frequently, higher mortality rates are seen, as are higher rates of rebleeding.

Non-selective beta-blockers are similarly used for primary prophylaxis in gastric varices. Endoscopic cyanoacrylate glue injection is another option for primary prevention of hemorrhage. Once hemorrhage has occurred, rubber band ligation, injection of cyanoacrylate glue and TIPS are again therapeutic options. Balloon-occluded retrograde transvenous obliteration (BRTO) is a technique used in Japan, and gaining greater acceptance in the US, in which a balloon-inflated catheter is used to access the shunt contributing to the varix. A sclerosing agent is then introduced through the catheter; after 30-50 minutes the catheter is withdrawn. In those with gastric varices caused by isolated splenic vein thrombosis, splenectomy or partial splenic embolization represents definitive management [43, 46-49].

Bleeding esophageal or gastric varices should be appropriately managed before attempting PEG placement. Non-bleeding varices (and other portal hypertensive gastropathies) should be approached carefully. They are considered a relative contraindication to PEG due to the risk of trauma with gastrostomy placement as well as the risk of post-PEG bleeding from the portal hypertension they herald.

GASTRIC OUTLET OBSTRUCTION

Gastric outlet obstruction (GOO) usually presents with nausea, vomiting and inability to tolerate oral intake. Both benign and malignant pathology can result in GOO, either by causing stricture or compression of the pylorus or proximal duodenum. Traditionally, benign causes, most commonly stricture secondary to peptic ulcer disease, have been the most prominent form of GOO, however, in the era of PPIs, malignancy has predominated [50, 51].

Benign gastric ulcer disease has become less frequent since it has been recognized that *H. pylori* and NSAIDs cause the majority of peptic ulcer disease. *H. pylori* can be eradicated with a regimen of antibiotics and acid suppressing medication, while NSAIDs can be stopped entirely in many patients [52]. Benign obstructions can often be treated endoscopically with balloon dilatation (Figure 7). This treatment may require several sessions for therapeutic benefit to become apparent and enduring, but it offers a minimally invasive alternative for those patients with comorbidities who may not tolerate a surgical approach [53, 54]. For those who fail endoscopic management or who wish for a more aggressive approach, surgical bypass may be performed (most often by gastrojejunostomy) either in an open or laparoscopic fashion.

In the Western world, malignant gastric outlet obstructions are most often caused by pancreatic cancer, followed by periampullary cancer, gastric cancer and cholangiocarcinoma. By the time malignant obstruction is discovered, the prognosis is usually quite poor with a short life expectancy. There are several options for palliation including endoscopic stenting and surgical bypass [55, 56]. Several studies have shown that endoscopic stenting is a safe and effective means of palliation that is associated with lower morbidities compared with surgical gastrojejunostomy, however the reintervention rate is higher [57, 58].

Figure 7. A) Gastric outlet obstruction (GOO) with associated ulceration..

Decompressive PEG for palliation can be considered if there is a portion of gastric wall uninvolved in tumor burden for safe positioning of gastrostomy. If the PEG is being used for enteral feeding, consideration should be given to placing a jejunal extension beyond the GOO as many patients with chronic GOO do not tolerate intra-gastric feeding as a result of gastric dysfunction from chronic obstruction.

Figure 7B. Balloon dilation of GOO with endoscopic visualization through balloon.

POLYPS

Fundic Gland Polyps

Gastric polyps come in many different forms, the most common of which are fundic gland polyps. Fundic gland polyps are found in 1-25% of EGDs and most often represent sporadic polyps or those associated with PPIs. They are similar in appearance to normal gastric mucosa, have a broad base and frequently are found in multiple (i.e., not singular) (Figure 8). These have a low chance of malignancy and do not require biopsy unless they exceed 1 cm in diameter. Those associated with PPIs can improve with discontinuation of the PPI.

Hyperplastic Polyps

Hyperplastic polyps, found most frequently within the antrum of the stomach, are caused by an inflammatory condition such as chronic gastritis, *H. pylori* and pernicious anemia. They can be sessile or pedunculated, are usually less than 2 cm and can be associated with ulceration and bleeding. It is recommended that biopsies of the surround tissue be taken to identify the underlying cause. Although the incidence of malignant change within these polyps is low, they are associated with increased risk of cancer within the stomach. Those that are greater than 1 cm should be excised completely. These can resolve with treatment of the underlying disorder.

Figure 8. Gastric fundic gland polyps.

Adenomatous Polyps

Adenomatous polyps represent a similar pathologic process to that seen in colon polyps and are precancerous. They are usually flat and found within the gastric antrum or duodenum (Figure 9). Those that are greater than 2 cm and those with villous histology have a greater chance of harboring malignancy. It is recommended that these polyps be fully excised and a surveillance program initiated. [59, 60] Patients with known polyposis syndromes, such as familial adenomatous polyposis (FAP), should have foregut screening included in their long term surveillance, and use of a side viewing duodenoscope to optimize periampullary visualization may be helpful in such settings. Polyps are not a contraindication to PEG placement.

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) is an increasingly common condition in the United States with up to 25% of adults experiencing symptoms weekly [61]. GERD results from abnormal relaxation of the lower esophageal sphincter (LES) outside of swallow initiation or from an incompetent LES. This causes abnormal exposure of the esophagus to gastric acid which manifests as pyrosis, regurgitation and dysphagia.

GERD is frequently treated empirically, most often with PPIs, H_2 antagonists or antacids. In many this leads to resolution of symptoms. Weight loss and other lifestyle changes such as avoiding nighttime meals, elevating the head of bed and avoiding chocolate, coffee, carbonated beverages, tobacco and alcohol, can also aid in alleviating symptoms. For those who do not respond to empiric treatment, it is recommended that EGD be performed to evaluate for complications, such as esophageal erosion or Barrett's esophagus (discussed

previously), or for an alternative diagnosis. Diagnosis of GERD can be confirmed with ambulatory pH monitoring [61-63].

Ambulatory pH monitoring is performed by placing a probe 5 cm proximal to the LES either transnasally or by endoscopy. Episodes of esophageal pH < 4 are recorded and categorized as reflux episodes. This data can be used to calculate a DeMeester score, which factors in the amount of time (frequency and duration) or acid exposure, with a score of more than 14.72 indicating pathologic reflux. The DeMeester score is specifically obtained by taking into account the number of reflux episodes, the duration of those episodes, the total time with a pH < 4, and the upright versus supine time with a pH < 4 [64].

For patients with chronic symptoms who do not wish to commit to lifelong medical therapy despite successful medical management, for those who fail medical therapy, for those with complications of GERD or for those with extraesophageal symptoms, there are surgical options for the treatment of GERD. Fundoplication has a cure rate up to 90% or greater, with esophageal acid exposure proven to be less than those successfully controlled with medical management [65, 66]. Prior to surgical therapy, there must be objective evidence of GERD, whether through EGD findings such as erosion, Barrett's esophagus or peptic stricture or through pH monitoring. Many patients will also undergo esophageal manometry, employed to rule out esophageal dysmotility disorders that may be a contraindication for surgery or define an impaired clearance component to the reflux diathesis, and barium swallow, to further delineate anatomy. Surgery is then individualized for each patient as these procedures can include several different types of fundoplication, and can be performed in either an open, laparoscopic or even robotic fashion [67].

Intragastric feedings via PEG in patients with GERD can lead to aspiration. Transpyloric PEG feedings with a jejunal extension tube do not eliminate the risk of aspiration, and either direct PEJ or surgical jejunostomy can be considered.

Peptic Ulcer Disease

Peptic ulcer disease (PUD) once represented one of the most common causes of presentation of the acute abdomen. As mentioned previously, with the discovery of *H. pylori* and the widespread use of PPIs, complications such as perforation, hemorrhage and stricture are increasingly less common. Gastric ulcers are associated with post-prandial pain with resulting in weight loss, whereas the pain of duodenal ulcers are often relieved with ingestion of food leading to weight gain. They can be seen throughout the stomach and in the duodenum as depressions of the mucosal surface and may extend into the submucosal tissue layers or beyond (Figure 10).

Gastric ulcers are classified based on their location. The type of ulcer suggests the underlying cause and, therefore, guides treatment. Type I ulcers are the most common making up 60% of gastric ulcers and are found on the lesser curvature. They are not associated with acid hypersecretion and most are caused by *H. pylori* infection. *H. pylori* is treated by a 14 day regimen of antibiotics and acid suppression, with subsequent documentation of eradication. Type II ulcers are comprised of both ulcers on the lesser curvature and within the duodenum. They are associated with acid hypersecretion as are type III ulcers. Type III ulcers are pre-pyloric. Types II and II are both treated with acid suppression. Those ulcers refractory to acid suppressing medication should be evaluated for Zollinger-Ellison syndrome. Type IV

ulcers are near the GEJ and are specifically classified because of the anatomic challenges of their surgical management; and type V are associated with NSAIDs and can be located throughout the stomach. Type V ulcers are treated by cessation of the offending medication and the addition of an acid suppression medication. Patients with ulcers refractory to medical management may be candidates for partial gastrectomy (including excision of the ulcer) with reconstruction, with or without vagotomy, with the latter generally being reserved for settings with acid hypersecretion.

Duodenal ulcers are also caused by *H. pylori* and acid hypersecretion. Similar treatment regimens exist for duodenal ulcers [68, 69].

All ulcer patients should undergo gastric biopsy to establish whether *H. pylori* infection is present. Gastric ulcers should themselves be biopsied to rule out malignant changes. Ulcers associated with *H. pylori* do not require reevaluation by endoscopy unless; the biopsy demonstrates dysplastic changes, symptoms are not resolving with medical treatment or, the patient has complications of the ulcer such as bleeding, perforation or stricture. Successful *H. pylori* eradication can be confirmed non-invasively via the urea breath test [70].

PUD is not a contraindication to PEG placement but the presence of disease should be documented in the endoscopy note in case the patient develops bleeding following PEG placement which may not be secondary to the gastrostomy puncture.

Figure 9. Duodenal adenomatous polyp.

GASTROINTESTINAL STROMAL TUMORS

Submucosal pathology is not uncommonly seen during EGD. Gastrointestinal stromal tumors (GISTs) are the most common neoplasm of mesenchymal origin within the GI tract. These tumors arise from the interstitial cells of Cajal, which serve as pacemaker cells within the bowel. They are predominantly found within the stomach and small intestine, but can be found elsewhere within the GI tract. Many are asymptomatic and are found on routine imaging; others present with bleeding, early satiety or pain. On endoscopy they are seen as submucosal masses that are often exophytic in nature (Figure 11). GISTs have malignant

potential but rarely metastasize. Diagnosis is often based on clinical characteristics and biopsy is not required [71]. Mucosal biopsies alone are often nondiagnostic, and biopsy under endoscopic ultrasound guidance may be performed where tissue sampling will affect treatment.

The mainstay of treatment remains complete surgical excision. In elderly patients that are poor operative candidates, small GISTs (<2 cm) may be kept under surveillance. There have been recent reports of endoscopic enucleation and resection via endoscopic submucosal dissection (ESD) with good results [72]. Pathological examination is needed to determine whether adjuvant therapy is required. Risk factors for malignant GIST include mitotic index, size and location. Most GISTs are *KIT* positive and respond favorably to tyrosine kinase inhibitors, the most commonly used of which is imatinib.

The presence of a GIST on endoscopy is not a contraindication to PEG, but appropriate diagnostic and therapeutic follow-up must be arranged. Surveillance following successful excision (if performed) consists of annual imaging for five years [73, 74].

Figure 10. Non-bleeding gastric ulcer.

GASTROPARESIS

Gastroparesis represents delayed gastric emptying in the absence of mechanical obstruction, with symptoms including abdominal pain, postprandial fullness, early satiety, nausea, vomiting and weight loss. As a sensorimotor disorder, its exact etiology is unknown but related disease processes include long-standing, poorly controlled diabetes, medications (such as narcotics and anticholinergics), connective tissue disorders, prior upper gastrointestinal surgery, specifically in association with vagotomy, and others. Gastroparesis is found more predominantly in female patients, and a depletion of the interstitial cells of Cajal have been implicated. Diagnosis is confirmed by gastric-emptying scintigraphy with delayed emptying seen at four hours. Endoscopic findings of retained food bezoar within the stomach after an overnight fast are also pathognomonic for gastroparesis (Figure 12) [75, 76].

Several treatment options exist for gastroparesis. Management begins with dietary changes by adopting smaller, more frequent meals that are low in fat. Medications such as promotility agents (metaclopramide or erythromycin) and psychotropic medications may then be added. Surgical and endoscopic options also exist. Gastric neurostimulation utilizes electrical impulses to stimulate the stomach. Temporary wires are placed endoscopically and the wires exteriorized either through a PEG tube or transnasal. If neurostimulation improves symptoms during a temporary trial, a neurostimulator may be surgically implanted. Endoscopic or surgical pyloroplasty reduces the resistance of gastric drainage and can be a useful adjunct in refractory disease. Transpyloric stenting and injection of botulinum toxin into the pylorus have also been described, but are associated with the potentials for stent migration and need for repeat treatments, respectively. Radical treatment includes subtotal or total gastrectomy with reconstruction, but is reserved for truly refractory cases [75-78].

Figure 11. Large gastric GIST.

Figure 12. Retained gastric food bezoar in a patient with gastroparesis.

If significant weight loss occurs as a result of gastroparesis, it may be necessary to place an enteral feeding tube. In this clinical situation, PEG (alone) is contraindicated and direct percutaneous endoscopic jejunostomy (PEJ) or percutaneous endoscopic gastrostomy with jejunal extension tube (PEG-JET) may provide more benefit as these procedures bypass the nonfunctional stomach and allow for distal feeding. The PEG-JET allows for feeding via the J-limb as well as providing ventilation through the G-limb. They are associated with a need for more frequent hardware changes as they become clogged more frequently than the traditional PEG. If these procedures are unsuccessful percutaneously, they may be performed surgically. An additional option includes traditional PEG with the placement of an extension into the jejunum by interventional radiology [79-80].

CONCLUSION

The endoscopist performing PEG will encounter potentially unexpected upper gastrointestinal pathologies in a not-insignificant number of cases. A complete endoscopic examination of the esophagus, stomach, and duodenum is vital. Identifying such pathology is an important potential advantage of PEG compared to other gastrostomy techniques. It may not only guide the need for further intervention, but affect the decision making regarding PEG placement. Recognition of the common pathologies described, along with a working knowledge of their appropriate management, is an important skill for the endoscopist performing PEG placement.

EDITOR'S COMMENT

This chapter details the importance of performing a complete endoscopic exam at the time of enteral access placement. The implications of identified anatomical/pathological abnormalities need to be well understood by the endoscopist, as well as the need for subsequent surveillance of pathology. Although many abnormalities identified will have minimal impact on patients with limited life expectancy, it is also very important to fully document these findings in the procedural report. (JMM)

Chapter 128

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY: THE ‘PULL’ TECHNIQUE

Kyle L. Kleppe, MD and Melissa Phillips LaPinska*, MD

University of Tennessee Graduate School of Medicine, Knoxville, TN, US

INTRODUCTION

Medical providers have long recognized the importance of nutritional support in patients who are critically ill or undergoing medical or surgical interventions. Enteral access has been shown to be superior when compared to parenteral access for this purpose with reduced infectious complications, cost benefit, and immune-related advantages. The percutaneous gastrostomy tube (PEG) is the most common form of enteral access performed. There are two main methods for PEG tube placement: the ‘pull’ technique which will be described in this chapter and the ‘push’ technique which will be described in Chapter 8. Together, these two approaches for oral insertion represent the most common approach for endoscopic gastrostomy tube placement.

Originally, all patients needing enteral access required a laparotomy for gastrostomy tube placement. Endoscopic gastrostomy tube placement radically transformed the approach for gastrostomy tube placement, transitioning it from a surgical to an endoscopic approach. The pull technique was the original method first described by Drs. Ponsky and Gauderer in 1980 [1]. Although the technique has subsequently undergone refinement, the core features remain the same [1, 2]. Experience with the pull technique has been well documented in the literature with excellent safety record and outcomes.

* Corresponding Author’s Email: MSPhillips1@utmck.edu.

PATIENT PREPARATION AND SEDATION

The patient is prepared by fasting for 8 hours prior to the planned endoscopic procedure to decrease the risk of aspiration. This fasting period should include discontinuation of enteral feeds as well as oral intake. Prophylactic antibiotics should be routinely administered within one hour of the procedure in all patients undergoing PEG tube insertion using the ‘pull’ method. Antibiotic administration is associated with a significant reduction in peristomal and abdominal wall infections [3]. Coverage should be focused on coverage of skin flora and it is the authors’ practice to administer cefazolin unless contradicted by patient allergy or established antibacterial resistance. Patients must also have intravenous access for the administration of sedation and systemic analgesics. The patient is placed in the supine position on the endoscopy table. The upper abdomen is clipped of hair and prepped using chlorhexidine or another antimicrobial agent.

The endoscopy suite should be prepared with all necessary supplies for either sedation with monitoring or, under select circumstances, general anesthesia. All patients must have heart rate, blood pressure monitoring, and pulse oximetry throughout the entire procedure. Capnography may be available in many endoscopy units and can be utilized at the provider’s preference. A dedicated member of the team should monitor for adverse sedation-related events and be able to provide rescue measures if required. Step-wise titration of medication is performed until the patient has reached the desired level of sedation. This most commonly involves a narcotic and a benzodiazepine, although many endoscopy areas are now strictly using propofol with the assistance of an anesthetic provider. General endotracheal anesthesia is considered for patients who cannot maintain airway safety and in patients at increased risk for aspiration. More details regarding patient preparation and sedation are available in Chapters 2 and Chapters 5 respectively.

STEP-BY-STEP TECHNIQUE FOR THE PULL TECHNIQUE

1. Perform a Full Upper Endoscopy

After adequate sedation, the endoscopist should introduce the gastroscope through the mouth and advance it into the stomach. If difficulty is encountered with passing the gastroscope in the supine position, rolling the patient into a modified left lateral decubitus position by elevating the right shoulder should help with this. Other considerations for difficult passage include upper airway obstruction which can be relieved by a jaw lift or obstructing oral pathology, as may be the case when enteral access is needed for oropharyngeal cancer. If malignant obstruction is present and the endoscope is unable to pass, one must consider either an introducer technique or a laparoscopic assisted gastrostomy. See Chapter 9 for additional details on these methods.

Once access to the esophagus has been intubated, care should be taken to evaluate the esophagus and esophageal hiatus for pathology, specifically for a paraesophageal hernia or for signs of esophageal stricture. The most important part of the complete upper endoscopy is to evaluate for and rule out gastric outlet obstruction by passing the gastroscope through the pylorus and into the second portion of the duodenum (see Chapter 6 for additional details).

Following this, the gastroscope is withdrawn into the stomach to insufflate. Full gastric insufflation allows the anterior wall of the stomach to be in direct contact with the anterior abdominal wall without intervening viscera between the two structures.

2. Identify the Site for PEG Placement

The anterior abdominal wall is examined for the site of maximal transillumination where the light of the gastroscope is most strongly seen through the anterior abdominal wall (Figure 1). This site represents where the inflated stomach is most closely approximated to the anterior abdominal wall without intervening viscera. It may be necessary to turn off the room lights to see this, particularly in patients with morbid obesity. Multiple sites may be evaluated with transillumination before selecting the best site using this technique in combination with direct palpation. It should be noted that transillumination may be identified at non-ideal locations or in a concerning pattern suggesting that PEG should not be performed (Figure 2).

Figure 1. Abdominal wall transillumination at the site of planned PEG.

Figure 2. Abnormal transillumination patterns during PEG endoscopy. A) Peri-umbilical. B) Right lower quadrant. C) Diffuse abdominal illumination (including illumination of colonic haustral folds).

Figure 3. Sight selection for PEG. A) A finger is used to indent the abdominal wall at the location of best transillumination. B) The endoscopist observes for clear one-to-one motion of the gastric wall with abdominal palpation.

To assess for this, the assistant should gently depress the abdominal wall with one finger, beginning 2 cm below the costal margin near midline. The endoscopist should see the gastric wall indent simultaneously in a one-to-one fashion with palpation of the abdominal wall (Figure 3). The initial site chosen should be between the greater and the lesser curve of the stomach (to avoid major vasculature). Ideally, placement of the PEG should be located distally in the body of the stomach or in the proximal antrum as this location allow for easier insertion of the jejunal extension through the gastrostomy tube, also known as a PEG-J feeding tube, if indicated for poor gastric motility. Care should be taken to avoid selecting a site within one centimeter of the costal margin as this area is typically more uncomfortable for the patient.

3. Perform the “Safe Tract” Technique

Once the ideal location has been selected using the transillumination and one-to-one palpation detailed above, the “safe-tract” method is then used to confirm that no intervening viscera, specifically loops of bowel, are between the stomach and the anterior abdominal wall. This is performed by slowly advancing a small-caliber needle, such as the local anesthesia needle included in most PEG kits, attached to a syringe filled with fluid through the abdominal wall while negative pressure (aspiration) is applied to the plunger (Figure 4A). The endoscopist, using the gastroscope, should visualize the needle entering the stomach at the same instance the assistant sees air within the syringe outside the abdominal wall (Figure 4B). If air is seen in the syringe before the needle is visualized in the gastric lumen, the needle has passed through another hollow viscus, likely the colon or small bowel, rather than entered directly into the stomach. If blood is visualized, it is presumed that the needle has encountered the left lobe of the liver interposed between the stomach and abdominal wall, the epigastric vessel behind the rectus muscle one of the named vessels supplying the stomach (e.g., gastroepiploic). In either of these settings, the location choice should be reevaluated and a repeat safe tract performed before proceeding. Once the safe tract technique confirms an appropriate location for the PEG, the selected site is infiltrated with local anesthesia. The authors believe the “safe-tract” technique, above transillumination and direct palpation, to be the most reliable method for identifying the best site for PEG introduction.

Figure 4. Safe tract technique. A) Finder needle is advanced through the abdominal wall while aspirating with the syringe. B) Endoscopic view of the finder needle entering the gastric lumen. The needle tip should be visualized at the same time as bubbles are seen in the syringe to confirm a safe tract.

4. Gain Access to the Gastric Lumen

After preparing the area with antiseptic prep, a skin incision should be made in the transverse direction using a #11-blade through the area where local anesthetic was infiltrated. An incision that is larger than the PEG tube, leaving space around the tube, decreases the incidence of peri-tubal infections by allowing efflux of bacteria that are introduced during the passage of the gastrostomy through the oropharynx. For a standard 20-French tube, the external diameter is 6.7 mm and the calculated length of the required incision to allow for adequate drainage is 10.5 mm in length. The stomach should be kept insufflated throughout the procedure to ensure contact of the gastric and abdominal walls. The endoscopist should position an open snare through the working channel of the gastroscope against the anterior stomach wall at the anticipated entry site (Figure 5A). The needle/cannula assembly is then introduced through the anterior abdominal wall incision (Figure 6) and into the gastric lumen under the direct visualization of the gastroscope. If performed correctly, the snare should be in an appropriate location to immediately secure the cannula (Figure 5B). The snare is closed, securing the cannula and the introducer needle is removed (Figure 5C).

5. Placement of the Guidewire

The looped guide wire is passed by the assistant through the cannula on the abdominal wall and the endoscopist uses the snare to grasp the wire (Figure 5D). The endoscopist then withdraws the endoscope, snare, and guide wire through the patient's mouth. Care must be taken to avoid pulling the guide wire through the abdominal wall, and losing access to the stomach.

Figure 5. A) Endoscopic snare is opened and placed against the gastric wall at the site of planned PEG (note the small blood spot from the safe tract needle). B) Needle and cannula are passed through the gastric wall and through the appropriately placed snare loop. C) The snare is subsequently closed to secure the cannula. D) Guidewire is passed through the cannula. The snare is opened, releasing the cannula, is repositioned, and subsequently closed around the guidewire.

Figure 6. Introduction of the needle/cannula assembly through the abdominal wall.

6. Assembly of the ‘Pull’ PEG

The PEG tube contains an all-in-one apparatus that has a long flexible tube with internal bumper and a short stiff dilating end attached to a small pre-looped wire (Figure 7). To secure the PEG tube to the guidewire, pass both strands of the guidewire through the wire loop dilator end of the feeding tube, then pass the internal retention-bumper of the feeding tube

between the strands of the insertion guidewire. Pulling tightly forms a knot (Figure 8). Water-soluble lubricant is applied to the stiff short dilating end to facilitate passage.

The endoscopist may use the snare to hold the internal retention-bumper of the PEG, allowing the endoscope to be pulled into the esophagus as the PEG is pulled into the stomach (Figure 9). Reinsertion of the endoscope allows one to assess the gastrostomy site for hemostasis and ideal length of the tube in relationship to the subcutaneous tissue; however, studies have not shown this to be an absolute requirement when performing the procedure. The easiest way to grasp the PEG with the snare is around the internal retention bumper rather than around the tubing itself (Figure 10). This configuration not only folds the bumper into a lower-profile configuration, but permits the tube to be easily released from the snare within the esophagus. It also places the endoscope, snare and tube in an in-line configuration rather than forcing the tube to be at a right angle to the scope and snare.

Figure 7. Pull PEG tube.

Figure 8. Joining a 'pull' PEG to the guidewire. A) Both strands of the guidewire are passed through the wire loop at the end of the PEG dilator. B) The strands of the guidewire are separated. C) The internal retention bumper of the PEG is passed between the guidewire strands. D) The guidewire and wire loop are pulled opposite one another (1) to form a tight knot (2).

Figure 9. Endoscopic snare is used to grasp the internal-retention bumper of the PEG allowing the gastroscope to be pulled into the esophagus along with the tube thus facilitating esophageal reintubation. Inset shows the endoscopic view.

Figure 10. Correct positioning of the snare on the PEG bumper folds the retention dome and places the tube and snare in a straight line. Incorrect positioning places the snare around the tubing itself creating a 90° angle.

7. Insertion of the ‘Pull’ PEG

Apply gentle pressure to the abdominal side of the guide wire, advancing the tapered PEG tube and endoscope to enter the mouth and then the esophagus. If the endoscope is being reintroduced to reassess PEG placement, when the endoscope reaches the 30-cm mark the endoscopist should open the snare to release the bumper. The endoscopist should then remove the snare from the working channel of the gastroscope. The assistant will continue to apply gentle traction on the guidewire to advance the PEG into the body of the stomach under direct endoscopic visualization. After the tapered portion has exited the anterior abdominal wall, the flexible portion of PEG will be seen (Figure 11).

8. Confirm Position of the PEG Tube

The assistant will apply gentle pressure to confirm that the internal bumper of the PEG tube is engaged on the stomach wall (Figure 12A). Care should be taken to avoid overt traction of the tube (and more importantly the bumper) against the anterior portion of the

abdominal stomach to prevent a “buried bumper” syndrome. The endoscopist, having followed the PEG into the stomach, visualizes the entry site and confirms hemostasis. The external portion of the PEG is then assembled per manufacturer’s recommendations. Visual confirmation of adequate position of the external bumper (which should be snug but not tight against the gastric wall) is the final maneuver prior to securing the catheter before removal of the gastroscope (Figure 12B). The endoscopist should note the centimeter marking at the level of the skin and record it in the patients chart for future reference if tube migration is ever questioned. The external tube clamp (if included in the kit) can be applied as well as the feeding adapter (Figure 13).

TECHNICAL VARIATIONS

Second-Look Gastroscopy

After placement of the PEG tube, the gastroscope is often returned to the stomach to confirm adequate position of the internal bumper and assess for other complications such as bleeding. Some practitioners have challenged the need for this as changes in tube position are required in a minority of patents. One study demonstrated adjustments in tube position was made to only 7% of patients and felt that repeat endoscopy is not routinely required [4].

Figure 11. Rigid dilating portion of the PEG has traversed the abdominal wall and the flexible portion of the tube is visible. Note the two-finger counter-traction being applied to the abdominal wall.

Figure 12. Final PEG bumper position. A) Endoscopic view of the internal bumper shows it is lightly touching the gastric mucosa. B) External bumper is lightly touching the skin surface and easily turns when spun.

Figure 13. Final PEG assembly. A) The soft portion of the tubing is cut to desired length. B) The tubing clamp (if provided) is applied. C) The feeding adapter is applied. D) The caps are closed.

A technique for rapid re-insertion has been described utilizing a rat tooth forceps through the biopsy channel of the endoscope grasping the center hub of the mushroom catheter allowing the endoscope to be drawn into the esophagus and stomach as the tube is pulled into the mouth [5]. It is the authors' practice to perform repeat endoscopy to confirm placement. We utilize the included snare within the kit placed around the mushroom to allow for rapid re-introduction of the scope into the stomach to confirm visualization as described above.

Gastrointestinal T-Anchors

If the endoscopist desires to use gastrointestinal T-anchors, they can be placed at this time (Figure 12B). It is not routine in the authors' practice to use these for a routine pull PEG although they are commonly used in other techniques for PEG such as the introducer technique or in high-risk patients.

Low Profile Tubes

Newer devices allow for delivery of low profile tubes utilizing the pull technique. The tube is a one piece device that has several predefined lengths. The introducer needle had external markings to measure the thickness of the anterior abdominal wall. An appropriately sized tube can then be selected. The external flange is housed within the dilator portion of the device and is deployed once it has been pulled externally (Figure 14). The authors frequently utilize this type of tube in the pediatric population to prevent larger external aspects on the feeding device.

Figure 14. Low profile pull type PEG. A) Dilating portion of the tube houses the collapsed external bumper and cap. B) Endoscopic view of the internal bumper. C) View of the external bumper after completion of the procedure.

GASTROSTOMY USE

There is considerable variability in the timing of utilization of the tube for nutrition and medications in the literature and by individual practitioners. Several manufacturers recommend the patient to remain without enteral feeding for 24 hours. PEG feeding can safely begin 3 hours after tube placement if there are no problems with placement [6]. Post-operative fasting length was found to be shortest in the pull technique when compared to other technique [7]. It is authors' practice to utilize the tube immediately after the procedure for medications and to begin enteral feeding at three hours post PEG placement in the medically stable patient.

CONTRAINDICATIONS AND COMPLICATIONS

A general list of contraindications for orally introduced PEG placement are listed in Table 1. These are additionally detailed in Chapter 2. Specifically with the pull technique, one must pay special attention to head and neck cancers as gastrostomy site metastasis, although rare, has been reported. The oral insertion technique may also be difficult or impossible if there is stricture in the oral cavity or esophagus due to inflammatory process, radiation, or cancer. The endoscope may not be able to pass or the PEG tube itself may not pass. Alternative methods, such as the introducer methods and radiologically or surgically placed gastrostomy tubes, may be required in this situation.

CONCLUSION

The 'pull' technique is a commonly used standard method for placing endoscopic feeding tubes. Careful selection of the appropriate patient and the use of additional steps such as the "safe tract" technique, has created an excellent safety profile for this method has allowed for its wide adoption.

Table 1. Absolute and relative contraindications to PEG

Contraindications and considerations	
Absolute	Relative and Special Considerations
Nonfunctioning or obstructed upper GI tract (exception of use for decompression)	Upper aerodigestive tract malignancy (<i>head and neck vs esophageal</i>)
Presence of peritonitis	Massive ascites
Sepsis	Severe malnutrition
	Infectious processes of stomach and abdominal wall
	Proximal small bowel fistulae
	Portal hypertension
	Coagulopathy
	Morbid obesity
	Previous abdominal surgeries
	Hiatal hernia
	History of peritoneal dialysis
	Peritoneal carcinomatosis
	General decompensation

EDITOR'S COMMENT

This chapter describes the indications and techniques for one of the commonly used approaches to gaining enteral access. The choice for one technique over the others should be based on patient indications rather than merely personal experience. Although physicians may surely have personal preferences, endoscopists should become familiar and skilled in all alternatives for placement of enteral access tubes (JMM).

Chapter 129

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY: THE ‘PUSH’ TECHNIQUE

Keyur Parikh¹, MD and Richard C. K. Wong^{1,*}, MD

¹University Hospitals Case Medical Center, Cleveland, OH, US

ABSTRACT

Since the development of the PEG over 3 decades ago by Gauderer, Ponsky and Izant in 1980, it has been a widely adapted technique to help establish long-term enteral feeding for patients worldwide [1]. As a result, there have also been several different endoscopic methods to perform the procedure including: the ‘Pull’, the ‘Push’, the ‘Introducer’, and the ‘Single-step button’. There are surgical and radiological methods as well. The two most commonly used techniques in the placement of PEG’s are the ‘Push’, which is described in this chapter, and the ‘Pull’, which is described in detail in Chapter 7.

TECHNIQUE OVERVIEW

While the original PEG technique described in 1980 was ‘Pull’, the ‘Push’ technique was later described by Sacks, et al., in 1983 [2]. Essentially, this technique is very similar to the ‘Pull’ method for PEG except that a more durable single guidewire is passed into the stomach instead of a more flexible looped guidewire (or suture). Since the development of PEG, there have been several comparative studies to help determine which technique is superior as judged by means of complication rates, dislocation rates, and ease of use.

A recent retrospective study in 2015 by Kohler, et al., compared 231 patients who underwent PEG via either Push (100) or Pull (131) technique and found that there was a significantly increased incidence of complications with the ‘Push’ technique 33% vs 21.4% ($p=0.047$) [3]. It is important to note that a vast majority of these were considered minor, Clavien-Dindo grade 1 (97.8%), complications meaning that no additional intervention was

* Corresponding Author’s Email: Richard.wong@uhhospitals.org.

necessary. Additionally they found that rates of tube dislocation and occlusion were significantly higher with the 'Push' technique in comparison to the 'Pull'. Older retrospective studies have also suggested similar findings [4].

One of two prospective randomized-controlled trial was performed by Hogan, et al., in 1986. In that study, 40 patients were randomized to either technique. Difficulty of technique was considered similar as per endoscopist reports. The 'Pull' technique had a 40% minor complication rate, including 4 patients with peristomal inflammation, 2 with purulent drainage and 2 with an easily replaced tube dislodgement. The 'Push' technique had a 10% minor complication rate with 1 patient with purulent drainage and 1 with an easily replaced tube dislodgement. Reported major complications were similar for both groups and were 20% for the 'Pull' and 15% for the 'Push' techniques. In the 'Pull' group, 1 patient developed a subcutaneous abscess, 2 patients developed aspiration, with 1 passing away, and 1 patient developed peristomal leakage. In the 'Push' group, 1 patient had a tube dislodgement requiring a repeat procedure, 1 patient died from aspiration, and 1 had peristomal leakage. Overall, they concluded that although there was a high number of patients with minor complications, 25% of the group, these were reported for the purposes of a study and overall those were not truly clinically significant. They found that complication rates between both groups were similar [5].

A second prospective randomized-controlled trial was performed in Spain by Fernandez, et al., in 1995. In this study, 44 patients were randomized to either technique. No differences were found between the two procedures in terms of technical difficulty or complications. Minor site infections occurred in 3 patients from each group, which resolved with topical antibiotic therapy. No procedure-related mortality was reported in either technique. Three tube dislodgements were observed in the 'Pull' technique group [6].

For patients with advanced head and neck cancer, the author's practice is to preferentially use the 'Push' technique. A retrospective study by Tucker, et al., in 2003 found a statistically significant increase in complications with the 'Pull' technique compared to the 'Push' technique (30 vs. 0%; $p = 0.006$). The majority of complications, again, were minor and required no additional invasive intervention; however, there were no reported major or minor complications with the 'Push' technique [7].

Based on the results of these studies, at the present time, use of 'Pull' or 'Push' technique for gastrostomy rests upon the endoscopist's preference.

PRE-PROCEDURE PREPARATION

As for any non-urgent endoscopic procedure, the patient is prepared by withholding gastric feedings for generally 6-8 hours before the procedure. A thorough assessment of the patient should be performed prior to scheduling the procedure. This includes a review for the indication of the procedure. The patient's anatomy should be understood and any altered gastroesophageal anatomy should be known prior to PEG placement. Small bowel feeding should be considered in patients with known gastroparesis (eg. PEG with jejunal extension (PEG-J) or direct percutaneous endoscopic jejunostomy (D-PEJ)). A careful review of medications should be performed, specifically, to evaluate for agents that would place the patient at increased risk of bleeding.

As noted in Chapter 4, recent updated guidelines by the American Society for Gastrointestinal Endoscopy (ASGE) indicate that monotherapy with aspirin/NSAIDs or clopidogrel are considered low risk for bleeding in patients undergoing PEG placement and do not need to be held prior to the procedure (this does not apply to dual antiplatelet therapy, which is considered high risk for bleeding) [8]. For patients on warfarin or the newer anticoagulants (anti-thrombin inhibitors, anti-Xa inhibitors), we generally bridge with heparin if they are on longer-acting agents, but for medications with shorter half-lives, these are held for the appropriate time interval prior to the procedure [8]. In addition, it is important that the endoscopist discuss peri-procedure management of antiplatelet and anticoagulant medications with the prescribing medical provider.

Finally, and often most importantly, the ethical considerations of PEG should be considered. Placement of a feeding gastrostomy is certainly appropriate when it is anticipated to improve a patient's quality of life. It is clear that nasoenteric tube feedings may be equally effective (using dedicated small caliber nasoenteric tubes), are less invasive, and more appropriate in patients with limited potential for survival. As such, it is important to approximate what period of time enteral feedings may be required. If a PEG is being performed simply for the purpose of prolonging life in an otherwise unsalvageable situation, the authors strongly advocate for a careful consultation with family members and the managing medical provider, and an evaluation of overall goals of care prior to deciding whether or not a PEG should be performed. See Chapter 3 for a more detailed discussion of this topic.

Within 30 minutes of PEG placement, a single prophylactic dose of an antibiotic is given. The authors use a first generation cephalosporin and begin to administer the dose immediately prior to the start of the procedure. A 2002 study found that infectious complications without the use of routine pre-procedure antibiotics were as high as 38% and current ASGE guidelines recommend the use of intravenous cefazolin (or an antibiotic with equivalent coverage) within 30 minutes of the start of the procedure [9-11]. Patients who are allergic to penicillin should receive a single one-time IV dose of vancomycin for prophylaxis. In addition to providing adequate prophylaxis against local or systemic infection, this step is an important metric in measurement of procedure quality. In the age of value-based medicine, meeting these metrics is an important part in delivering high-quality medical care to patients.

'PUSH' TECHNIQUE

The patient is placed in supine position on the bed in the procedure room and the abdomen is exposed. Some endoscopists use a topical anesthetic agent for the throat; however, we do not use this in all patients. Sedative drugs are administered intravenously under appropriate anesthesia monitoring. Once adequately sedated a complete and careful esophagogastroduodenoscopy (EGD) is performed to evaluate for any endoscopic findings that would change patient management and/or prevent safe placement of PEG (See Chapter 6). It is important to mention that introduction of the endoscope may occasionally be difficult with the patient in the supine position and may be facilitated, if necessary, by rolling the patient to his or her side or by using a chin-lift maneuver to straighten passage. After the EGD, the first step in PEG is to find the appropriate location for placement.

When the endoscope is positioned in the body of the stomach, it should be fully inflated. During this time, the lights in room should be dimmed, if not done previously. The authors prefer the use of carbon dioxide rather than air for insufflation during endoscopy as this is easily reabsorbed with improved patient comfort. Full distension of the stomach is an important step for several reasons. First, it displaces the liver in a cephalad direction and the colon towards the pelvis. Second, full gastric distention brings the anterior gastric wall in contact with the peritoneal surface. Third, it allows for trans-illumination of light from inside the stomach to the external surface. All of these measures help prevent risk of traumatic solid organ injury and inadvertent puncture of the colon or small bowel during this procedure by helping to ensure there is no intervening viscera.

Endoscopically, it is important to choose a location for PEG placement that is proximal to the gastric angularis because puncture of the antrum may damage the gastric pacemaker and could result in gastroparesis. The external location of the PEG should generally be in the left upper quadrant of the abdomen, approximately two fingerbreadths distance from bony structures such as the xiphoid process and costal margin.

Figure 1. Localization of the gastrostomy site. It is important to choose a site proximal to the angularis approximately 2 fingerbreadths distance from bony structures. A) Endoscopic view of the gastric body before and B) after pressing down with one finger on the abdominal wall. C) External view and internal view should show good one-to one finger indentation.

Figure 2. Transillumination will help guide direct puncture of the abdominal wall at the selected location for PEG placement.

Figure 3. Safe-Tract Technique. A) The external anesthetic needle is B) visualized endoscopically. Bubbles should not be seen in the syringe until the needle is seen in the stomach breaching the mucosa.

The chosen location should be the site where there is the best one-to-one finger indentation of the stomach (Figure 1), where trans-illumination (Figure 2) can be readily visualized, and where there are no intervening air bubbles between the skin and the site of gastric puncture using the 'safe-tract' needle aspiration technique [12]. This will be the site for the PEG and it should be marked on the skin with a sterile pen. The skin may need to be shaved if there is excessive surface hair.

Once the site is selected, all subsequent steps are performed using standard aseptic technique. The skin is then aseptically cleaned using an appropriate agent. The patient's skin should be anesthetized with local anesthetic. Then, with constant negative pressure on the syringe after the anesthetic needle enters the skin, the needle is inserted into the stomach until the needle is visualized endoscopically with air bubbles only being seen in the syringe when the needle breaches the gastric mucosa (Figure 3). This so-called, 'safe-tract' technique, once again, ensures that there are no intervening gas-containing viscera between the abdominal wall and the stomach. If air bubbles are seen before the needle enters the stomach, then a different site should be chosen.

Next, approximately a 1cm incision is made at the site and blunt dissection performed with a hemostat (Figure 4). Then, the puncturing cannula (needle) within a plastic catheter is inserted into the stomach through the incision and visualized endoscopically (Figure 5A). At this time, a snare loop should be used to seize the cannula (Figure 5B). After this, the inner stylet is removed, and a sturdy 0.035' guidewire is passed through the cannula (Figure 5C).

The snare loop is tightly closed around this wire (Figure 5D) and the wire is carefully withdrawn along with the gastroscope from the patient's mouth while continuously maintaining a tight grasp of the snare loop around the wire.

It is very important that the assistant is tightly holding the other end of the wire outside the skin so that full control is maintained of both ends of the wire at all times during the procedure.

Figure 4. A) An approximately 1-cm horizontal skin incision is made at the site of planned puncture. B) Blunt dissection of the subcutaneous tissues is performed with a hemostat.

Figure 5. Guidewire access of the stomach. A) The puncturing needle with a plastic cannula is inserted in to the stomach through the incision site and visualized endoscopically. B) At this time, the snare loop should be used to seize the cannula. C) The puncturing needle is removed. D) A sturdy guidewire is passed through the cannula and the snare loop is then tightly closed around the wire. Following this, the wire is carefully withdrawn along with the endoscope *per os*.

Figure 6. Push gastrostomy insertion. A) Once the wire is out of the patient's mouth, it is released from the snare and grasped by the endoscopist. In this figure, both ends of the wire are held by the endoscopist for demonstration purposes. B) A Push-type gastrostomy tube with a rigid dilator end is threaded over the mouth-end of the wire. Both ends of the wire are held taut (one by the endoscopist one by the assistant) so that the wire is relatively straight and not bent. The lubricated gastrostomy tube is then carefully pushed over the mouth-end of the wire and into the stomach. C) As the dilator end of the gastrostomy tube emerges from the abdominal wall, the wire is released and the tube is grasped and carefully pulled the rest of the way to its final position. Note that constant counter-pressure is being applied to the abdominal wall with two fingers on either side of the tube.

Once the wire is out of the patient's mouth, it is released from the snare, and the mouth-end of the wire is grasped by the endoscopist (Figure 6A). A 'Push'-type gastrostomy tube is threaded over it with a rigid dilator end towards the patient.

It is very important that both ends of the wire are held taut (so that the wire is relatively straight and not bent) as the lubricated gastrostomy tube is carefully pushed over the wire and into the stomach (Figure 6B).

As the dilator end of the gastrostomy tube emerges from the abdominal wall, the wire is released, and the tube is grasped and carefully pulled the rest of the way to its final position while maintaining constant counter-pressure on the abdominal wall with two fingers on either side of the tube to reduce risk of abdominal wall injury (Figure 6C). The connection between the rigid dilator and the softer gastrostomy tube is the widest portion of the tube and thus it is important that the initial incision has been wide enough and that blunt dissection has been adequately performed to prevent significant resistance during passage of the tube (Figure 7).

An external plastic bumper is placed over the PEG tube and the final anchoring position is adjusted so that the external bumper is only lightly touching the skin (there should be about a 1cm gap in-between the skin and the external bumper). The authors prefer a plastic "T" bar as the external bumper as it is more comfortable for the patient (Figure 8).

In addition, although not mandatory, the authors prefer to re-intubate the stomach in order to provide photo-documentation of the final position of the intra-gastric PEG bumper (Figure 9). The tube can then be cut to length and have the external clamp and feeding adaptor placed.

Figure 7. The connection between the rigid dilator and the softer gastrostomy tube is the widest portion of the tube. It is important that the initial skin incision has been made wide enough and that blunt dissection has been adequately performed to prevent resistance during passage of the tube through the skin and subcutaneous tissues.

Figure 8. The external plastic bumper is placed over the PEG tube and the final anchoring position is adjusted so that the external bumper is only lightly touching the skin. There should be about a 1-cm gap between the skin and the external bumper.

Figure 9. Endoscopic view after re-intubation of the stomach in order to provide photo documentation of the final position of the internal PEG bumper.

EDITOR'S COMMENT

The authors describe one of the commonly utilized techniques for gaining access during percutaneous endoscopic gastrostomy tube placement. The components of the procedure are well delineated and endoscopists must pay attention to these details to allow for safe and effective PEG placement. The use of safe tract technique and appropriate indications should be utilized for all PEG placements (JMM).

Chapter 130

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY: INTRODUCER TECHNIQUE

Sean B. Orenstein*, MD

Oregon Health & Science University, Portland, OR, US

INTRODUCTION

Since its inception by Drs. Ponsky and Gauderer in 1980, percutaneous endoscopic gastrostomy (PEG) tube placement has revolutionized and simplified gastric feeding access [1]. The ability to place a gastrostomy tube in a minimally invasive fashion has allowed surgeons, gastroenterologists, and other clinicians to provide safe and efficient enteral nutrition to innumerable patients in need. While little has changed in the overall design and procedural flow of PEG tube placement, several technique modifications have been developed to provide enteral access to a wider variety of patients. One such modification is the “Introducer Technique,” first described in 1980 by Hashibal, but popularized by Russell et al. in 1984 [2, 3]. Using endoscopic guidance, the gastrostomy tube (G-tube) is inserted directly through the abdominal wall via the Seldinger technique into the gastric lumen utilizing a peel-away sheath, akin to placing a central venous catheter over a wire with a sheath. Radiographic techniques without the use of endoscopy have also been described for direct percutaneous gastrostomy tube placement, and are routinely used among radiologists [4-7]. This chapter provides an overview of the introducer technique, including applicable patient population, advantages and disadvantages and technical considerations of the method.

ADVANTAGES, DISADVANTAGES AND INDICATIONS

There are several advantages of using the introducer technique. While endoscopic guidance during G-tube placement is desirable, the introducer technique can be employed without the need for endoscopy as long as there is either sufficient extraluminal visualization during tube placement (e.g., laparoscopic or open) or controlled radiographic guidance (e.g.,

* Corresponding Author’s Email: orenstei@ohsu.edu.

computed tomography or fluoroscopy). A major advantage with introducer techniques described in the literature is reduced infection rates when compared to the pull and push techniques, likely as a result of oral cavity flora being dragged through the abdominal wound with the latter. This is supported by a small handful of prospective randomized trials that have demonstrated significantly lower peristomal infection rates with the direct introducer technique. A meta-analysis of 16 studies likewise favored the introducer technique, with significantly higher wound infection rates reported when using the pull technique (OR 13.0; $p < 0.0001$) [7-10].

Another benefit is the ability to place multiple types of G-tubes using the introducer technique (e.g., traditional PEG tubes, balloon-based tubes, Foley or Malecot catheter, and others), giving both the endoscopist and patient numerous options to choose from for appropriate tube sizing and selection. The introducer technique also permits the placement of low-profile button-type G-tube without the need for exchanges in clinic. Last, several case series exist that demonstrate malignant metastases at PEG tube sites when using the pull technique in patients with active oropharyngeal or esophageal malignancies [11-14]. While it is unclear if this is due to direct exfoliation and dragging of malignant cells into the PEG site or other forms of dissemination, the series' authors recommend utilizing the push or introducer technique when faced with oropharyngeal or esophageal malignancies.

The introducer technique is not without disadvantages; it tends to be more technically challenging given the need to safely pass multiple objects (needle, wire, dilators, sheath, tube) through the insertion site. There is also, theoretically, a greater risk of injuring or perforating the posterior gastric wall with the wire and dilators during sequential dilations. Compared to the introducer technique, the traditional pull technique simplifies this by requiring only a single pass of the needle and wire, with auto-dilation of the tract during external withdrawal of the tube.

Indications for using the introducer technique can be general or population-specific. Many endoscopists routinely utilize this technique when electively placing a G-tube, though certain pathologic conditions may warrant the need for an introducer technique over the pull or push techniques. If there are contraindications to oropharyngeal or esophageal manipulation such as after traumatic injury, perforation, recent instrumentation, obstruction, or high risk for iatrogenic injury with G-tube placement, the introducer technique should be considered. Having a history of head and neck malignancy, radiation or recent resection may make oropharyngeal manipulation challenging [15]. Likewise, a history of esophageal diseases such as malignant masses, stricture or obstruction, history of radiation therapy, recent resection with friable and edematous tissue, as well as other pathologies may make tube placement difficult and potentially dangerous if the internal retention portion of the G-tube is to be pulled through the esophageal lumen. In these situations, the ability to completely bypass the oropharynx and esophagus with tube placement reduces iatrogenic risks to the areas of concern.

Supplies

While it is possible to obtain the items separately, manufactures produce convenient all-in-one kits that contain the majority of the necessary instruments and supplies including (Figure 1);

- Gastrostomy tube: 18 and 20 French (Fr) are common sizes though there exist are a wide variety of sizes for various body habitus' and uses. Tube type is based on endoscopist and patient preferences. The introducer technique allows placement of a wide variety of tubes. Tube types include traditional Ponsky® PEG tubes (balloon-less with protruding tubing), MIC-KEY™ (low profile tubes that stay relatively flush to skin; require attachment of an external tube during feeding; internal balloon), other balloon-based tubes, Foley catheter or Malecot tube, and others.

Figure 1. Introducer PEG kits. A) Kimberly Clark 20 Fr introducer kit with SAF-T-PEXY™ T-fasteners and all in one dilator and peel-away sheath. B) Ross 18 Fr introducer gastrostomy kit with Brown/Mueller T-Fastener™ and serial (12, 16, 20, 24 Fr dilators).

- Guidewire: flexible 0.035" guidewire with a J-shaped tip
- Dilators: serial dilators or all-in-one telescoping dilator (Figure 2).
- Peel-away sheath: it is critical to ensure that the sheath lumen size will accommodate the chosen G-tube size (Figure 3). Some kits do not include a peel away sheath but rather include a stylet that fits into the gastrostomy permitting it to pass over the wire (Figure 4)

- Lubricating jelly
- Gastropexy supplies: most kits will include gastrointestinal T-anchors (Figure 5). Alternative methods include laparoscopically placed size 2-0 slowly resorbable sutures (3-4) sewn as seromuscular bites. Alternatively, laparoscopic suture passer can be use under endoscopic or laparoscopic (or both) to deliver trans-abdominal, transgastric sutures.

Figure 3. A) Peel-away introducer sheath. B) With the gastrostomy tube balloon inflated within the stomach, the sheath is cracked and peeled away.

Figure 4. A) 18 Fr gastrostomy tube and stylet B) Stylet and gastrostomy assembled and ready to be passed over the wire through the already dilated tract.

For a narrowed oropharyngeal or esophageal lumen, slim gastroscopes are available that have outer diameters less than 5 mm. Such modern ultraslim gastroscopes contain 2 mm working channels to allow for instrumentation. If instruments will be utilized (e.g., snare, grasper), ensure the size is compatible with the working channel diameter. A standard-sized gastroscope may be used if no obstructing pathology present.

Figure 5. Gastrointestinal T-anchors; SAF-T-PEXY™ T-fasteners (left) and Brown/Mueller T-Fastener™ (right).

Technique

Setup

The patient is positioned supine and slight reverse-Trendelenburg if they are a high aspiration risk. Having the left arm tucked is helpful for transitioning to/from endoscopy. The endoscope should be easily accessible near patient's head on working side, with monitor(s) in clear view by all team members. If the patient is intubated, tape the endotracheal tube to right side of the mouth, adjacent to or though the side of the bite-block.

The abdomen can be prepped locally for an endoscopic only method while wide prepping and draping of the entire abdomen is required for a laparoscopic approach. This ensures adequate exposure of the epigastrium and lower chest.

If laparoscopy is used, typically 3 trocars are required, with one camera port and two working ports for gastropexy suture placements. Five mm trocars can be routinely used for two of the ports, however, a 10-12 mm trocar is typically necessary for needle/suture insertion. Alternatively, three 5 mm ports can be used with a ski needle or if a laparoscopic suture passer is being employed for the gastropexy stitches. An additional right upper quadrant port may be necessary for liver retraction.

Endoscopy-Only Approach

Endoscopic guidance allows for assistance with tube placement as well as confirmation of intraluminal placement. If there is no oropharyngeal or esophageal pathology, a standard gastroscope is advanced into the gastric body. A slim or ultraslim gastroscope should be used if there is a question of intraluminal narrowing from a mass, stricture, swelling, etc. This slim scope can be passed transnasal in the event of significant oral pathology. A gastroscope with a working channel is advisable in case the need arises for grasping or snaring.

Insufflating the stomach with gas, preferably carbon dioxide (CO₂) due to its rapid post-procedure resorption, allows for easier identification of optimal tube location as well as adds a layer of safety by providing more working space for suture placement and wire/dilator/tube manipulation. The expanded stomach should abut the epigastrium with external finger pressure, thus providing an optimal target for tube location.

A site on the anterior gastric wall should be chosen for tube placement. The central gastric body is an ideal location, however, the patient's anatomy may necessitate a different location for tube placement. A high-riding stomach may require a more inferior and distal tube placement. If the tube is placed distally in the stomach, be sure tubes with balloons do not obstruct the gastric outlet. The skin is marked with a skin marker to identify the proposed site of gastrostomy placement and a safe-tract method performed to confirm the safety of the proposed location.

Gastrointestinal T-anchors (typically 3-4) are then placed surrounding the proposed location in a triangle or square configuration and secured (Figure 6A). These gastropexy sutures will permit the dilators to be more easily pushed through the gastric wall without the tissue catching on the dilators and causing collapse of the gastric lumen. The remainder of the procedure then proceeds as described below in *Tube Placement*.

Figure 6. Endoscopic view of introducer method of PEG placement. A) Gastrointestinal T-anchors are placed to perform a gastropexy. B) Introducer needle and J-tipped guidewire are passed. C) Over the wire, dilators are introduced to sequentially dilate the tube tract. D) Peel-away sheath remains across the gastrotomy. E) Gastrostomy tube is introduced through the sheath, which is subsequently cracked and peeled away. F) Gastrostomy balloon is inflated, securing the tube within the gastric lumen.

Figure 7. Trocar placement for laparoscopic-assisted approach to introducer gastrostomy. Peel-away sheath shown in center of three trans fascial gastropexy sutures.

Laparoscopic-Assisted Approach

If laparoscopic access is being used, obtain desired abdominal access (optical vs Veress vs Hassan) at or near the umbilicus with a 5-mm trocar, utilizing a 5-mm laparoscope for versatility in camera port placement. This should be performed before any endoscopic gastric insufflation is performed to reduce the risk of an access-related injury. Subsequently, one 5-mm trocar is placed to the right of mid-epigastrium and one 12-mm trocar is placed in the left upper quadrant (Figure 7). This 12-mm trocar permits easy passage of needles for the placement of gastropexy stitches. Alternatively, a 5-mm trocar can be used to pass ski needles or assist a suture passer-only method of gastropexy described below in *Endoscopic-Assisted Gastropexy*. Gentle atraumatic clamping of the distal stomach will assist with maintaining gastric insufflation. If no upper endoscopy is available or feasible (e.g., complete obstruction) the procedure can proceed with trans-abdominal-only approach. However, confirmation of proper intraluminal placement should be performed with a contrast radiographic study via the feeding tube following case completion.

After performing any necessary adhesiolysis, the stomach is mobilized enough to provide wide access to the anterior gastric wall. Using gentle atraumatic grasping, the anterior gastric wall is retracted anteriorly towards the abdominal wall in the epigastrium to test for sufficient reach to the abdominal wall. The abdomen may require partial release of CO₂ insufflation along with setting a lower insufflation pressure to allow retraction without tearing the stomach. Endoscopic insufflation of the stomach aids in identifying proper tube location by pushing the gastric wall anteriorly. If no endoscope is used, the guidewire introducer needle can be used to insufflate the stomach. A site on the anterior gastric wall should be chosen for tube placement. The central gastric body is an ideal location, however, the patient's anatomy may necessitate a different location for tube placement. A high-riding stomach may require a more inferior and distal tube placement. If the tube is placed distally in the stomach be sure tubes with balloons do not obstruct the pyloric channel. The skin is marked with a skin marker to identify the proposed site of gastrostomy placement.

Laparoscopic gastropexy provides a useful way to "tripod," or suspend, the stomach in order allow streamlined tube placement as well as subsequently fixate the stomach to the abdominal wall. Three or four separate gastropexy sutures are placed laparoscopically using size 2-0 slowly-resorbable sutures, with good seromuscular tissue purchase (Figure 8). After each suture is placed, a stab incision is made in the skin, and a laparoscopic suture passer is used for trans-fascial retrieval of the suture. A surgical clamp is used to secure both suture tails externally. To maximize visualization of the gastric wall it is helpful to place one suture superiorly around 12 o'clock and two separate sutures inferiorly at approximately 4 and 8 o'clock. The sutures are typically suspended just enough to permit visualization of the space between the anterior abdominal wall and the anterior gastric wall and are not tied until after complete placement of the g-tube (Figure 8). The sutures can be loosened somewhat in order to manipulate the stomach into position, providing a "tripod" effect thus allowing direct visualization of the gastric wall during tube placement. Because trans-fascial sutures can be painful, it is advisable to inject local anesthetic into the fascia and peritoneum prior to pulling the stomach up all the way with the sutures. Alternatively, pre-packaged T-fasteners can be used for this step under direct endoscopic visualization. Some surgeons prefer to place the T-fasteners following completion of tube insertion.

Figure 8. Laparoscopic view of three transfascial gastroplexy sutures adjacent to the falciform ligament and a 12 mm laparoscopic trocar.

Endoscopic-Assisted Gastroplexy

If gastrointestinal T-anchors or laparoscopic suturing methods are not available or not desired, gastroplexy can be performed with endoscopic assistance. There are two primary methods by which this technique can be performed.

Figure 9. Laparoscopic suture passer method of gastroplexy. A) Suture passer and suture are delivered through the abdominal and gastric wall. B) The suture is grasped with an endoscopic grasping forceps and the empty suture passer is withdrawn. C) The empty suture passer is delivered at a new location. D) The endoscopic forceps returns the suture to the suture passer for removal, completing the gastroplexy stitch.

After making a small stab incision with a #11 blade, a laparoscopic suture passer is delivered through the abdominal and gastric walls pulling a suture with it. The suture is secured within in the gastric lumen with an endoscopic snare or grasping forceps passed through the gastroscope. The empty suture passer is withdrawn and delivered at a new fascial/gastric location but through the same skin incision. The endoscope is used to pass the tail of the suture to the empty passer and the suture is withdrawn, completing the gastropexy (Figure 9). This is repeated until 2-4 gastropexy sutures have been placed around the planned location for the gastrostomy.

Figure 10. Angiocatheter method of transfascial gastropexy. In this case, a permanent suture is being placed in between two temporary gastrointestinal T-anchors A) A skin nick is made with a #11 blade. B) An 18 gauge angiocatheter is passed transfascial and transgastric under endoscopic visualization. C) Suture is passed through the catheter after the needle is removed. D) The catheter is removed as the suture is held by an endoscopic accessory passed through the gastroscope working channel. E) The angiocatheter is reintroduced and the needle removed. Through the angiocatheter, an unsheathed endoscopic snare is passed into the gastric lumen. The endoscope passes the suture through the loop of the snare. F) The snare is withdrawn, pulling the intragastric tail of the suture back to the skin surface. G) The two tails are untangled. H) Knots are tied to complete the gastropexy.

As an alternative, an angiocatheter can be used to deliver and retrieve the suture for gastropexy (Figure 10). After a skin nick has been made in the desired location with a #11 blade, an 18-gauge angiocatheter is passed through the abdominal and gastric walls under endoscopic visualization. The desired suture is passed through the catheter and is grasped with an endoscopic accessory (e.g., snare or biopsy forceps) within the gastric lumen. The catheter is removed over the suture, reloaded with the needle and passed through the abdominal and gastric wall a second time. The loop end of an unsheathed polypectomy snare (or a simple suture loop) is passed through the catheter. The endoscope accessory is then used to deliver the intragastric end of the suture through the snare loop. The snare is withdrawn, capturing the suture and pulling it back to the skin surface. This is repeated until 2-4 gastropexy sutures have been placed around the planned location for the gastrostomy. Knots are tied, completing the gastropexy.

Tube Placement

Guidewire Placement

With retraction of the anterior gastric wall, the large bore (e.g., 18G) introducer needle is inserted full thickness into the gastric lumen under endoscopic visualization. The flexible J-tip guidewire is inserted into the introducer needle (Figure 6B). Any resistance should prompt repositioning and replacement. Take great care to observe for gastric wall perforation, as even flexible tip wires can perforate or dissect through the gastric wall.

If no endoscope is available to verify intraluminal placement (laparoscopic or radiology only approach), the stomach should be insufflated with either air boluses or by attaching the needle to the laparoscopic CO₂ tubing for insufflation (Figure 11). The stomach should rapidly enlarge; any resistance to flow should prompt needle replacement as it likely within the gastric wall (submucosal) or has traversed the posterior gastric wall. Gentle atraumatic clamping of the distal stomach will assist with maintaining gastric insufflation. Once insufflation has occurred, the guidewire can be advanced and the needle removed (Figure 12).

Figure 11. Laparoscopic view of introducer needle entering the gastric body. The stomach is subsequently insufflated via this needle, confirming intraluminal position.

Figure 12. Laparoscopic view of J-tipped guidewire entering the gastric body.

Dilator and Sheath Placement

Introducer kits come with either separate serial dilators or all-in-one systems with sequential dilators that telescope over themselves. These are used to sequentially dilate the tract to the size of the peel-away sheath (Figure 6C). After insertion of the sheath the other dilators and wire are removed for tube placement (Figure 6D and Figure 13). Because of their rigidity and length, great care must be taken to avoid gastric wall injury or perforation with the dilators. Carefully observe the entire dilator and surrounding area during each passing of the dilator & sheath. While some resistance will be met when traversing the abdominal and gastric walls, any further resistance or difficulty with insertion should prompt retraction of the dilator. If no endoscope is being used (laparoscopic or radiology only method), measuring the abdominal wall thickness with either the needle, wire, or first dilator can help with judging the approximate length that resistance through the wall should be encountered.

Figure 13. Laparoscopic view of the peel-away sheath entering the gastric body.

Tube Insertion

Tube choice is based on surgeon and patient preference. With adequate lubrication on the distal end of the tube, including any inner flange or balloon, the tube is inserted through the sheath (Figure 6E). The use of a PEG-style tube, with internal plastic bumper, may require “taco” folding of the tip/bumper during insertion. The peel-away sheath is carefully broken

and slowly torn while the tube is inserted into the stomach (Figure 14). Care is taken to not inadvertently pull the tube out during final sheath removal. If using a balloon-type tube fill the balloon to the manufacturer's recommended volume with sterile water, as saline can crystallize over time. The balloon should be inflated as soon as the entire balloon is clear of the sheath tip to help prevent inadvertent tube pull during sheath removal (Figure 6F).

Figure 14. Peel-away sheath being removed from around a gastrostomy tube during a laparoscopic assisted introducer method PEG.

Gastropexy Completion

At this time the previously-placed gastropexy sutures can be tied down to the abdominal wall. Care should be taken to not apply excessive tension when tying as this can lead to tearing, ischemia or necrosis of the gastric wall.

Post-Procedure Care

Document the volume of fluid instilled into the balloon for later reference. The tube should be flushed with water to assess patency and ensure no kinking or tube malfunction. If endoscopy was not used during placement, a water-soluble contrast study can be obtained on the table with fluoroscopy, if available, or post-procedure in a radiology unit.

The tube should be able to spin freely without catching tissue internally or externally. Excess tension on the external bumper can lead to superficial pressure necrosis. Allow a small amount (0.5-1 cm) of excess tubing between skin and external bumper. To test this, gently bend tube near the skin level. Document the depth of the G-tube at level of skin, not at level of external bumper. Any post-procedural adjustments to the tube or external bumper should be documented for later reference. In general, it is not recommended to suture the external bumper to the skin as this can lead to superficial pressure necrosis as well as pain. However, certain circumstances may warrant suturing, such as if the patient is high risk for early tube withdrawal. Other options to reduce accidental tube dislodgement include taping the tube to the skin, loosely covering the abdomen with a binder, patient distraction, or restraints (if other options have been exhausted).

CONCLUSION

The introducer technique has emerged as an important minimally invasive gastrostomy technique. While endoscopic guidance is ideal in this procedure, it can be performed without an endoscope, thus allowing enteral access when upper endoscopy is either not feasible or available. Because the introducer technique relies on multiple passes through the gastric wall including serial dilation posteriorly into the stomach prior to sheath placement this method can be technically more challenging than other G-tube techniques. If performed in a safe and controlled manner, however, it is a highly useful technique in the armamentarium of minimally invasive gastrostomy procedures.

EDITOR'S COMMENT

This chapter very succinctly describes the introducer method of gastrostomy insertion, which can be performed under fluoroscopic, ultrasonographic, computed tomographic, laparoscopic or pure endoscopic guidance. This versatility has made the method a favorite among radiologists. As noted by Dr. Orenstein, the method has clear advantages when performed clinically for patients with cancers of the head and neck or esophagus (regardless of the degree of luminal obstruction). Familiarity with the technique will also permit surgeons to easily access the stomach and small bowel laparoscopically. (EMP)

Chapter 131

DIRECT PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY

Mena Boules, MD, Andrew Strong, MD and Matthew Kroh*, MD
Cleveland Clinic, Cleveland, OH, US

INTRODUCTION

Establishing durable enteral access for medication administration and delivery of nutrition is a common indication for upper therapeutic endoscopy. Since 1980, when it was first reported, the percutaneous endoscopic gastrostomy (PEG) tube has been a mainstay of enteral access [1-3]. In most clinical settings the PEG has replaced open gastrostomy tubes as the preferred method for enteral access. However, the PEG is not a panacea for enteral access. In certain patient populations, post-pyloric feeding has been demonstrated to be more appropriate, with corresponding better clinical outcomes [4, 5]. Furthermore, directed gastric feeding may be inadvisable, or contraindicated in patients with gastric outlet obstruction, post-vagotomy syndrome, gastroparesis, or pancreatitis. In these clinical scenarios, establishment of enteral access in the jejunum is preferable [3, 6].

In the short term, nasojejunal feeding can be established with or without endoscopic assistance. However, over longer periods of time and in the outpatient setting, trans-abdominal enteral access is preferred. Traditionally, open jejunostomy tube was surgically placed, later adapted as a laparoscopic technique; but both of these require general anesthesia. The first endoscopic technique for durable small bowel enteral access across the abdominal wall, was by means of introducing a small bore (8-10 Fr) jejunal extension tube (PEG-J) through a previously existing gastrostomy tube [7]. Successful in certain circumstances, PEG-Js may result in more frequent clogging and proximal migration of the jejunal extension retrograde into the stomach. Both scenarios result in the need for repeat endoscopy for revision or replacement [8, 9].

Direct percutaneous endoscopic jejunostomy tube (DPEJ) was first published by Shike et al. in 1987, as an adaptation of the pull PEG procedure, in 9 patients with prior partial- or

* Corresponding Author's Email: kroh@ccf.org.

total- gastrectomies [10]. In these patients, the surgically absent or surgically reduced gastric length, allowed access to the jejunum through an esophago-jejunostomy or gastro-jejunostomy with a standard upper endoscope. Since this initial description, applications of the technique have expanded, including placement in native and post-surgical settings (Figure 1 and Figure 2, respectively) [11, 12]. DPEJ placement is typically more technically challenging to perform, but when compared to the PEG-J, DPEJ tubes are less apt to kink or migrate back into the stomach [4, 13-16]. There is also the ability to place larger bore tubes, with decreased propensity to clog. [6] Due to this, rates of endoscopic re-intervention after successful initial placement of DPEJ tubes are less than PEG-J [17].

PATIENT SELECTION AND INDICATIONS

Patients should be considered for DPEJ if they meet two initial clinical criteria. First, that they are unable to maintain oral nutrition, but have a functional intestine suitable for enteral feeding. Second, a gastrostomy tube must be inadvisable, typically based on surgically altered anatomy, or functional gastric impairment. Generally accepted indications are patients with a need for enteral access with:

1. Documented gastroparesis and nutritional compromise
2. Prior bariatric operations with inadequate nutritional intake, and/or anastomotic complications
3. Prior total or subtotal gastrectomy where PEG is technically difficult or impossible
4. Esophageal or gastric malignancies, either for nutritional support during neoadjuvant therapy, or for palliation
5. High aspiration risk or severe GERD
6. Chronic pancreatitis
7. Need for administration of certain medications into the jejunum, such as L-dopa in the treatment of Parkinson's disease

Figure 1. Schematic of DPEJ tube in a patient with native anatomy.

Figure 2. DPEJ location following Roux-en-Y gastric bypass.

Contraindications to DPEJ include inability for the patient or a proxy to provide consent, large volume ascites, uncorrected coagulopathy, severe malnutrition where they are unlikely to heal, intestinal perforation or inability to undergo procedural sedation or general anesthesia. Patients with only short-term need for enteral feeds may be better served with naso-jejunal feeding. In our practice, the need for naso-jejunal feeding for greater than several weeks prompts consideration of DPEJ or laparoscopic jejunostomy. Moreover, in patients with a life expectancy of less than 30 days, this procedure may put the patient at risk for undue morbidity, and are better served with non-invasive or palliative measures.

TECHNIQUE

The initial report of successful DPEJ placement by Shike et al. was a modification of the pull technique for the PEG [10]. Since this description, technical modifications and alternatives have been published, including image-assisted techniques. We prefer to use a standard pediatric colonoscope or front-viewing diagnostic gastroscope, depending on the length needed to reach an appropriate segment of jejunum. Rumalla et al. detailed the technique well [18]. A number of commercial kits are available specifically for DPEJ; however, smaller diameter PEG tube kits (14-20 Fr) can typically be adapted as well.

DPEJ may be performed in an endoscopy suite, operative suite, or at the bedside with appropriate monitoring, as in the Intensive Care Unit. The patient is positioned supine on the procedure table. Conscious sedation may be used, and is typically accomplished using an opioid analgesic in combination with a benzodiazepine. General anesthesia may also be utilized, depending on setting, and facility capabilities.

Endoscope selection is based upon the patient's anatomy. If native anatomy exists, the use of a pediatric colonoscope provides sufficient length to reach a loop of jejunum distal to the ligament of Treitz. A standard upper endoscope may be used in patients with prior surgical resections and esophago-enteric or gastro-enteric anastomoses, wherein the jejunum is positioned more proximally [3, 19].

Advancement of the endoscope is continued until reaching the most proximal loop of jejunum that can be easily opposed to the abdominal wall. A discrete area of trans-illumination is identified on the abdominal wall. This candidate site is secondarily confirmed by finger indentation on the abdominal wall to create intra-jejunal localization by application of external pressure. The site is prepped and a finder needle is advanced while aspirating [20-22]. This safe tract technique is designed to identify the needle in the jejunal lumen simultaneously with aspiration of air in the finder needle. This helps confirm that no other air filled organ, e.g., colon, or adjacent small bowel, are inadvertently cannulated. After the finder needle localizes the appropriate location, a skin incision is made, and the needle with hollow cannula is inserted along the same trajectory. There are reports claiming that usage of a 21G needle is safer, due to a small potential iatrogenic puncture wound to other intra-abdominal structures, including interposed or adjacent loops of bowel [21, 22].

Upon successful endoscopic visualization of the cannula in the jejunum, an endoscopic snare grasps the cannula and stabilizes the jejunal loop to the anterior abdominal wall. Once this is successfully completed, the procedure is carried out in a similar fashion to a pull-type PEG, with advancement of a guidewire and tube placement (see Chapter 7 for additional technical description) [18]. Repeat upper endoscopy immediately after placement confirms correct position of the tube and evaluates the jejunotomy site for bleeding. Additionally, the position of the external bumper, and appropriate tension can be adjusted based on the endoscopic view. In most cases enteral feeding can begin within 24 hours.

There are published alternative methods for DPEJ placement. Some groups prefer a hybrid approach, utilizing endoscopy with the assistance of fluoroscopic guidance [23, 24]. Endoscopic insufflation provides air contrast on fluoroscopy and can simultaneously confirm the location of the endoscope, the bowel lumen, and guide needle trajectory. This advantage, however, requires additional personnel, training, and proper shielding [25]. There are additional reports utilizing double balloon endoscopy for DPEJ placement [26, 27]. This advanced endoscopic technique is likely best reserved as a rescue technique, when an orally passed colonoscope fails to reach a suitable jejunal loop for DPEJ placement.

SPECIAL CONSIDERATIONS IN PATIENTS WITH PRIOR FOREGUT SURGERY

In our practice, a large proportion of our referrals have had prior foregut surgery, which merits special consideration in terms of both specific nutritional complications and anatomy prior to placement of a jejunostomy tube. Patients with altered foregut anatomy may have a spectrum of macro- and micronutrient deficiencies, which can develop both early and late. Specific nutritional analysis is important, as deficiencies in calcium, vitamins D and B12, iron, and overall protein-calorie malnourishment are not uncommon. Post-foregut operative complications, such as marginal ulceration, stricture, and leak, all can also adversely affect a

patient's ability to tolerate oral intake. DPEJ can provide nutritional support, and bypass the affected anastomosis to better allow healing and promote enteral nutrition [14, 28, 29].

In general, patients who have previously undergone near-total or total- gastrectomy, Ivor-Lewis esophagectomy, pancreatoduodenectomy, Roux-en-Y reconstruction (for gastric bypass or other reason) or Billroth II, have a straighter and shorter course to reach the jejunum. In these circumstances, the site for DPEJ can typically be reached with a standard upper endoscope. Additionally, the reconstruction used, such as a Roux- or loop-jejunal limb, may be placed in an ante- or retro-colic position. Ante-colic position of the jejunal limb makes DPEJ technically easier and increases the overall successful placement rate.

Studies have shown improved DPEJ placement rates in patients with previous surgery when compared to those with native anatomy [19]. However, the endoscopist must understand the patients' current anatomy and the possible presence of both efferent and afferent jejunal limbs. In the case of Billroth II anatomy, the ampulla can serve as indicator of the incorrect, afferent limb. A consideration in post-Roux en-Y surgical anatomy is the possible presence of a "candy-cane" or "Bakers pouch" which exists when the anastomosis was formed in an end to side fashion. If the blind end of this anastomosis is particularly long, the endoscopist may errantly place a DPEJ in this limb. In post-surgical patients, consideration must be also given to the presence of post-operative adhesions, which may be an additional impediment or beneficial.

In some circumstances, adhesions may tether jejunal loops posteriorly, and make trans-illumination difficult, or fix intervening intra-abdominal structures between a target loop of jejunum and the abdominal wall. In other circumstances, adhesions may fix a desirable jejunal loop to the anterior abdominal wall. For this reason, patients that previously had a surgical jejunostomy tube can be excellent candidates for DPEJ, utilizing the same site, and the secured jejunal limb likely still adherent to the abdominal wall.

OUTCOMES

Reported success rates of DPEJ range from 68% to 100% [4, 11, 13-16]. One hundred percent success was reported by studies conducted by Barrera et al. and Shetzline and colleagues [4, 23]. The largest published study to date was conducted by Maple et al. which included 307 consecutive DPEJ attempts in 286 patients, and reports success in 68% of patients [11]. Several factors are speculated to contribute to this variable success rate, including technique variation amongst endoscopists, technique modification over time, and patient selection. Examination of patient selection criteria in this large study reveals a heterogeneous group, including patients with cancer (n = 80, 28%), gastroparesis (n = 61, 21%), history of previous upper GI surgery (n = 55, 19%), high risk of aspiration (n = 37, 13%), and other causes (n = 53, 19%) [11]. The highest success rate was achieved in patients with previous history of upper gastrointestinal tract surgery. This is similar to other reported studies [3]. The higher completion rate is accounted for by the gastro-enteric anastomoses, which functionally moves the small intestine more proximally. The more accessible position of the jejunum reduces difficulty in intubating the small intestine and may also provide additional fixation. Poor trans-illumination or difficulty intubating the jejunum accounts for most failures [3, 23].

COMPLICATIONS

Unsuccessful placement is the most common complication of DPEJ. Most often, unsuccessful placement is the result of inadequate or absent trans-illumination or failure to identify an appropriate safe tract for access. While interposed intra-abdominal structures or adhesive disease preventing apposition to the anterior abdominal wall contribute to failure rates; increased BMI also correlates with decreased likelihood of successful DPEJ placement [30]. One study queried pre-procedural abdominal computed tomography scans for factors predictive of DPEJ placement success and failure [31]. Both the skin to jejunum distance, and more so the abdominal wall thickness, predicted failure of DPEJ placement [31]. While cross sectional imaging would not be indicated for the sole purpose of predicting ease of DPEJ placement, in general, abdominal wall thickness should be considered prior to attempting percutaneous endoscopic access.

Complications in the immediate peri-procedural period include anesthesia-related complications such as aspiration, hypotension, and hypoxemia. Rarely bleeding from the insertion site can occur, and this is usually self-limited. The most feared, and most common major complication is tube dislodgement prior to maturation of the tract. The resultant peritonitis often requires operative intervention to close the enterotomy site and to control peritoneal contamination. The intraluminal location of the balloon or bumper of the tube, in a relatively small caliber jejunal lumen, lends to a greater likelihood of intraluminal mechanical intestinal obstruction. Overall, studies report complications ranging between 0% to 15% [3, 11].

Minor complications at the insertion site, including superficial infection, insertion site irritation or maceration, and peri-tube leakage may occur at early and late time periods. Rates for these complications are similar to that of PEG, and make up the majority of published complication rates [11]. Typically these can be solved with improvements to the local site and tube care. Pain at the insertion site can be a frustrating problem for both the patient and proceduralist, as both the etiology and a successful treatment regimen can be elusive. In these circumstances, physical exam or imaging should be used to identify any signs of localized abscess or tube dislodgement. Without findings of abnormality, intolerable pain at the insertion site may best be solved by removal of the tube, assuming there is a mature tract and another method for feeding or medication administration has been established.

Long-term complications are similar to other enteral access devices. Traction injuries on tube removal, although rare, can result in bowel perforation [32, 33]. Mechanical bowel obstruction and volvulus may be more common and unique to DPEJ tubes, when compared to surgically placed jejunostomy tubes. As DPEJ tubes lack secondary fixation points, the tube itself may act as the fulcrum for jejunal volvulus, which is minimized in surgically placed tubes by suture fixation at several sites on the abdominal wall [11]. Similar to other enteral access devices, DPEJ tubes are subject to the risk of fracture and degradation, estimated around 3% for PEG tubes, and similar for DPEJ [34].

Maple et al. also confirms an adverse events rate of 22.5% post-DPEJ placement. In a large (n = 286) series of patients, DPEJ resulted in a 10% overall complication rate (bowel perforation, bleeding, volvulus, chronic enterocutaneous fistula, and aspiration) [11].

Despite these drawbacks, DPEJ placement offers advantages over PEG-J and surgically placed jejunostomy tubes. DPEJ circumvents the proximal migration inherent to the jejunal

extension of PEG-J. Additionally, tube dysfunction is also reduced given the usage of a larger caliber tubes (16-20 French). Overall, DPEJ shows greater durability and reduction for re-intervention when compared to PEG-J [13, 17, 35]. When compared to surgically placed jejunostomy tubes, DPEJ avoids the need for general anesthesia, and morbidity of an open or laparoscopic surgical incision.

CONCLUSION

DPEJ is an effective technique with relatively low complications to provide durable enteral access directly into the small bowel for nutritional support and medication administration. This technique is particularly useful in patients with surgically altered foregut anatomy.

EDITOR'S COMMENT

Direct percutaneous endoscopic jejunostomy, particularly in the patient with native foregut anatomy, is a technically challenging procedure, requiring prior mastery of pull type PEG technique but also an understanding and acceptance by the endoscopist that it will have a higher primary failure rate. Knowing when it is not a technically feasible procedure is as important as being able to complete the task. Despite these limitations, it offers clear advantages over surgically placed jejunostomy tubes and PEG tubes with jejunal extension and should be considered in patients requiring durable post-pyloric feeding (EMP).

Chapter 132

PEG WITH JEJUNAL EXTENSION TUBE

Ryan R. Gaffney, DO and Matthew T. Moyer*, MD

Penn State Hershey Medical Center, Hershey, PA, US

INTRODUCTION

The delivery of enteral nutrition and medications to patients who have an intact and functional gastrointestinal tract but cannot sustain their caloric needs orally is essential to both acute, critical care and long-term care of patients [1]. The literature consistently demonstrates that enteral nutrition is preferred to parenteral nutrition for preservation of gut integrity, prevention of bacterial translocation, and downregulation of inflammation [2-3]. These effects ultimately translate into better clinical outcomes for patients including decreased incidence of infections, reduced chance for organ failure, and decreased hospital length of stay [4]. The ability to place gastric feeding tubes endoscopically in a percutaneous fashion has therefore become a major advancement in the delivery of nutrition therapy.

There are several clinical situations in which PEG alone is insufficient and placement of a more distal feeding tube to provide post-pyloric nutrition is advantageous. Jejunal feeding tubes are frequently used to minimize aspiration of gastric contents when gastric outlet obstruction or motility disorders preclude gastric feeding or when such feedings have resulted in tube feed-related aspiration [5]. In patients with severe gastroparesis, for example, percutaneous endoscopic techniques may provide two essential purposes: gastrostomy tube placement for decompression and jejunostomy tube insertion for facilitating enteral feeding [6].

Randomized trials and meta-analyses have evaluated the role of post-pyloric tube feeding compared with intra-gastric feeding in critically ill patients. Although heterogeneity exists among these studies, there is a trend towards reduced incidence of aspiration pneumonia with post-pyloric feeding [7-8]. In patients with recurrent episodes of chronic pancreatitis and nutritional compromise, placement of an endoscopic jejunostomy tube has been shown to reduce yearly hospitalizations and need for opiate analgesia [9]. For patients with altered surgical anatomy and/or non-operable luminal obstruction, enteral tubes directed distally past

* Corresponding Author's Email: mmoyer@hmc.psu.edu.

the lesion can be used for hydration and medication administration while providing decompression capabilities if a simultaneous gastrostomy tube is placed [10]. Table 1 summarizes patients who may benefit from the placement of a jejunal feeding extension via PEG.

Table 1. Indications for the placement of jejunal extension via a PEG

Clinical and Endoscopic Findings That Favor PEGJ Placement
Gastric outlet obstruction
Gastroparesis
Intolerance to gastric enteral feeding (high residual volumes, aspiration)
Pancreatitis
Gastro-enteric anastomotic issue (stricture, leak, fistula, etc)
Large hiatal hernia or findings suggestive of gastro-esophageal reflux on endoscopy
Proximal enteric fistula (distal esophagus, stomach, duodenum)
Superior mesenteric artery syndrome

CURRENT DEVICES

Once a careful clinical evaluation has identified the need for a jejunal feeding tube, awareness of patient-specific and technical factors becomes essential for proper tube choice and method of placement. A variety of percutaneous options for jejunal access are currently available from several manufacturers [5]. The initial choice of tube is often dependent upon a patient's anatomy and the presence or absence of a pre-existing percutaneous gastrostomy (PEG). For patients who have already undergone PEG tube placement, conversion of the PEG into a percutaneous endoscopic gastrojejunostomy (PEGJ) can be performed endoscopically with or without the aid of fluoroscopy [11]. These PEGJ devices are manufactured as a single-piece gastrojejunostomy tube with the jejunal portion permanently molded within a gastrostomy portion to allow one ostomy to perform venting through the gastric port and feeding through the jejunal extension (Figure 1). These devices are commercially available and are familiar to most gastroenterologists and surgeons are trained in the basics of PEG tube placement [12].

The PEGJ tube has an internal retention balloon that is inflated after placement to keep the tube positioned against the gastric wall. If a PEG tube has previously been placed, and a single single-piece gastrojejunostomy tube is desirable, conversion should wait a recommended 1 to 3 weeks following initial PEG placement to allow maturation of the new ostomy tract [10]. If gastropexy fasteners (gastrointestinal T-anchors) are available, however, this conversion can generally take place sooner, at the discretion of the endoscopist. The conversion is accomplished as follows; the existing PEG is removed and the single-piece PEGJ device is carefully advanced through the gastrostomy tract into the small bowel over a

guidewire (with or without fluoroscopic guidance). Alternatively, it can be endoscopically dragged into a post-pyloric position with a snare, forceps or endoclip.

Figure 1. Components of a single-piece percutaneous endoscopic gastrojejunostomy (PEGJ) tube. A) Gastric port for venting and decompression. B) Jejunal extension for administration of enteral feeds and medications. C) Internal retention balloon and balloon port. D) External appliance bolster. The length of the jejunal arm in this particular example is 45 cm, which sufficiently provides capabilities for deep enteral access beyond the ligament of Treitz.

Figure 2. Components of a jejunal extension tube. A) Gastric port. B) Jejunal port. C) Jejunal extension arm. The jejunal extension can be inserted simultaneously at the time of PEG tube insertion or at a subsequent endoscopy.

A second method for jejunal access in patients who have a PEG involves placement of a jejunal extension through the PEG tube (Figure 2). These extension tubes are commercially available kits that measure 8 Fr to 12 Fr in diameter and up to 90 cm in length to facilitate deep access beyond the ligament of Treitz [5]. Successful insertion of the extension tube is most commonly done endoscopically at the time of initial PEG tube placement as there is minimal to no further manipulation of the gastrostomy tract by placing this device. A variety of endoscopic methods have been described for successful placement of jejunal extension tubes and will be elaborated below. It is important to know that the jejunal adaptor is designed to fit the type of PEG tube being used, as there are proprietary differences between manufacturers that can result in tube incompatibility. This can result in inability to complete the procedure, tube malfunction and leak.

Following successful insertion, the jejunal extension tube is then fitted with a Y-adaptor that is used for tube feeding and flushing. The final tube position is usually confirmed with abdominal radiographs under fluoroscopy (Figure 3) and enteral feeding can be started immediately. While simultaneous placement of a jejunal extension tube during the same procedure as PEG insertion is convenient for patients and physicians, it has been our experience that the smaller caliber size and shorter length of jejunal extension tubes more commonly results in tube dysfunction (clogging and retrograde displacement into the stomach) as compared to the single-piece PEGJ devices (Figure 4). These complications unfortunately require re-intervention with another endoscopic procedure and can be very frustrating for patients, caregivers and clinicians.

For patients with abnormal anatomy precluding initial PEG placement into the stomach, direct percutaneous endoscopic jejunostomy (DPEJ) provides an endoscopic alternative for jejunal access (see Chapter 10) [13]. Direct PEJ tubes demonstrate greater longevity and decreased need for repeat intervention compared with PEGJ tubes but do so at a higher complication rate primarily because of difficulty identifying a safe access site for placement [14-15].

Figure 3. Spot radiograph demonstrating placement of a jejunal extension tube with injection of contrast through the jejunal limb opacifying loops of small bowel (arrowhead). The air signature of the greater curvature of the stomach is also apparent (black solid line).

Figure 4. Retrograde displacement of jejunal extension tubes into the stomach. A) Endoscopic view demonstrating gastrojejunostomy tube loop formation in the stomach body. B) Abdominal radiograph showing migration of a jejunal extension tube proximally into the stomach. Contrast injected into the jejunal limb opacifies the stomach. C) Computed tomography showing a PEGJ appliance that has coiled completely in the stomach.

TECHNICAL CONSIDERATIONS OF PEGJ

While significant progress has been made with both endoscopic insertion techniques and devices for deep jejunal access, PEGJ procedures remain technically difficult. Often they can be very trying and time consuming, and advanced training for their insertion may be variable depending on staff experience and available resources. The role of experience and interventional endoscopy training is therefore vital to consistent tube placement. Procedural success is also aided by adhering to important principles of PEG placement, with a few modifications.

Localization of the PEG in the antrum and not the body of the stomach is important to shorten the distance to the pylorus and straighten the insertion angle of the jejunal tube as it coarses from the stomach into the small intestine [16]. A site on the patient's anterior abdominal wall to the right of the midline at or above the umbilicus is usually preferable to achieve this [16]. In the event that the initial PEG was placed above the level of the antrum thereby creating a longer distance through the stomach for jejunal tube passage, we recommend insertion of the longest available jejunal extension tube through the PEG or preferably conversion of the PEG to a single-piece PEGJ. Our experience is that single-piece PEGJ devices have a larger diameter jejunal portion that affords higher reliability for keeping it post-pyloric, even if coiling occurs in the stomach.

Figure 5. Initial gastrostomy tube insertion for PEGJ. A and B, Outlining the costal margins and confirming “one to one” finger palpation with transillumination prior to PEGJ tube placement will help identify the appropriate site for enteric access. C, Safe tract technique is performed to avoid inadvertent tracking through an adjacent loop of bowel.

It is helpful to outline the relationships of the costal margins and the midline of the abdomen with an indelible marker just prior to PEGJ insertion. The optimal site should be localized by confirming endoscopic evidence of “one to one” finger palpation and transillumination of the endoscope light through the anterior abdominal wall if possible (Figure 5A, B). Intervening loops of bowel can be avoided by confirming a ‘safe tract’ for the guide sheath through the anterior abdominal wall directly into the stomach [17]. As a 10 ml syringe filled with saline is pushed inward, steady aspiration is performed to ensure that no bubbles or blood are seen in the syringe prior to entering the stomach (Figure 5C). If air bubbles appear in the syringe before the needle is visualized in the stomach, it is likely that there has been penetration through another part of the intestine and the position of the site should be re-evaluated.

Coiling of the jejunal tube in the stomach is a potential hindrance to successful placement. To help avoid this, use of a stiff endoscope is recommended. While many texts advocate use of a pediatric colonoscope, we typically have success using shorter, standard adult upper gastroscopes with an 8.8 mm outer diameter and 2.3 mm working channel as long as intubation into the third portion of the duodenal is possible [12, 16]. A longer endoscope (such as a pediatric colonoscope) may become necessary if patients with significant gastric distension (e.g., gastroparesis or gastric outlet obstruction patients) where much of the scope length is utilized simply by traversing the distended gastric body.

For wire-guided methods, the use of stiff 0.035-inch guidewires measuring 450-480 cm in length can also help reduce the tendency for coiling of the jejunal tube as it is passed over the wire. Wire and device handling should be facilitated by copious lubrication with a mineral oil or silicone-based oil. We typically flush the working channel of the endoscope with mineral oil prior to wire advancement and also lubricate the jejunal extension tube extensively before inserting it through the PEG. Several authorities also stress the importance of using an air retention valve or plug during jejunal extension tube placement to allow passage of a wire or snare through the gastrostomy without losing air insufflation [12, 16].

While air valves are available commercially in some PEGJ kits, one can be custom-made by cutting the cap off the port of a spare enteric feeding tube. The modified cap is then directly placed into the pre-existing PEG and the wire or snare inserted through the valve created in the cap and into the stomach. By serving as a barrier to ongoing air loss from the stomach during endoscopy, the air retention valve facilitates direct visualization of the stomach thereby preventing potential frustration for the endoscopist.

THROUGH-THE-SNARE TECHNIQUE

In our experience, the through-the-snare technique is the most reliable and least frustrating method for successfully placing a 9 or 12 Fr jejunal extension tube. As mentioned previously, this technique requires a pre-existing PEG tube (a 20 Fr PEG for a 9 Fr jejunal tube and a 24 Fr PEG for a 12 Fr jejunal tube), however the PEG can be placed during the same procedure. After cutting the PEG down to approximately 10 cm from the skin (Figure 6A), an endoscopic snare is passed through the PEG into the stomach (Figure 6B) and opened (Figure 6C). The esophagus is intubated with a standard upper endoscope or pediatric colonoscope. Upon reaching the stomach, the endoscope is navigated through the open snare and then is maneuvered post-pyloric and into the small bowel. Once the endoscope has reached the small bowel, the snare can be closed and opened once to ensure that it contains the endoscope. The position of the endoscope in the small bowel can be confirmed with fluoroscopic guidance, but this is not absolutely necessary. Once the scope has reach its deepest site of penetration into the small bowel, a long guidewire (at least 450 cm in length) is passed through the working channel of the endoscope into the jejunum (Figure 6D). The location of the wire can also be confirmed fluoroscopically. Using standard wire exchange techniques, the endoscope is then slowly withdrawn from the small bowel, leaving the guidewire distally.

Once the endoscope has been withdrawn into the proximal stomach (Figure 7A) above the level of the snare, the snare is closed on the guidewire to capture it and then pulled back through the PEG to the outside of the patient (Figure 7B). The loop in the guidewire is manually separated by the endoscopist. The proximal and distal aspects of the guidewire are then identified by gently pulling on the wire to visualize the end exiting the patient via the working channel of the endoscope. Once this proximal end of the wire is confirmed, it is pulled out completely through the PEG, resulting in a single, straightened guidewire grasped by the snare and passing through the PEG into the small bowel (Figure 7C). With the endoscope still positioned in the proximal part of the stomach, a lubricated jejunal extension tube is passed in position over the wire, through the PEG, and into the small bowel (Figure 7D). During this step, care should be taken to avoid putting substantial resistance on the guidewire as this could result in its displacement. Once successful placement is achieved (Figure 8A), the tube is secured by attaching an external bumper or bolster appliance over the PEG tubing next to the skin. At this point, additional components such as a C-clamp to keep the external tube closed and a Y-adaptor for tube feeding, flushing, and gastric aspiration can be attached (Figure 8B). Radiopaque contrast can be injected through the jejunal port of the Y-adaptor to confirm the location of the jejunal extension tube in the small bowel, but this is not absolutely necessary.

Figure 6. Through-the-snare technique for jejunal extension tube placement. A) PEG tube is cut down to approximately 10 cm from the skin surface. B) Endoscopic snare is passed through the PEG. C) Snare is opened to capture the endoscope which subsequently advances into the small bowel. D) A guidewire is passed through the working channel and extended beyond the scope (ideally beyond the ligament of Treitz).

Figure 7. Through-the-snare technique for jejunal extension tube placement (continued). A) The endoscope is brought back into the stomach while maintaining position of the guidewire in the small intestine. B) The snare is then closed on the guidewire to capture it and sequentially pulled back through the PEG, creating an external loop in the guidewire. C) The proximal loop carefully pulled through the PEG tube, leaving only a straightened guidewire that extends from across the PEG and into the small intestine. D) A well lubricated jejunal extension tube is advanced over the guidewire slowly and passed through the PEG and into position in the small bowel.

Figure 8. Through-the-snare technique for jejunal extension tube placement (continued). A) Endoscopic view showing the internal bumper of a gastrostomy tube placed at the level of the incisura with a 12 Fr jejunal extension inserted through the PEG and extending beyond the pylorus. Note the relative short angle that the jejunal extension tube makes as it coarses from the antrum towards the small bowel which is ideal for maintaining deep enteral access and avoiding retrograde migration. B) Newly placed PEG tube with jejunal extension and associated adapters.

OVER-THE-GUIDEWIRE TECHNIQUE

The fundamentals for the over-the-guidewire technique are based primarily upon carefully pushing a jejunal extension tube over a guidewire that has been successfully advanced into the small bowel and is held there manually. Similar to the through-the-snare technique, the over-the-guidewire technique involves placing a jejunal extension tube through an already created gastrostomy, therefore necessitating the need for PEG tube placement prior to or during the same procedure as jejunal extension tube insertion. This technique is made successful with endoscopic grasping devices that offer a secure grasp including those with distal teeth (rat-tooth forceps) or longer jaws (alligator-jaw clamp). Biopsy forceps are generally not as helpful for this procedure because they have jaws with limited capacity that cannot take hold of longer objects with a harder texture than tissue.

For this technique, a long guidewire with a length of at least 450 cm is passed through the PEG into the stomach. The esophagus is then intubated with a standard upper endoscope. Upon reaching the stomach, a rat-tooth forceps or similar grasping device is passed through the working channel of the scope to grasp the guidewire in the stomach and drag it into the jejunum (Figure 9A).

If a pediatric colonoscope or longer endoscope is used, longer grasping forceps will be necessary to maintain a sufficient working length beyond the tip of the endoscope. While maintaining a secure hold on the guidewire with the grasping device, the endoscope is advanced as far distally as possible to a depth at or beyond the ligament of Treitz. Once the endoscope has been inserted as far as possible into the small bowel, the guidewire is held in place in the small bowel by slowly advancing the biopsy forceps forward as the scope is backed out into the proximal stomach (Figure 9B). Once the endoscope is in the stomach, the jejunal extension tube is lubricated, and under direct endoscopic visualization, advanced over the wire, through the PEG, and beyond the stomach until it encounters the grasping forceps holding the guidewire in position in the small bowel (Figure 9C).

Figure 9. Over-the-guidewire technique for jejunal extension tube placement. A) A long guidewire is passed through a pre-existing gastrostomy tube and pulled into the small bowel with a grasping device. B) The endoscope is withdrawn into the stomach while maintaining guidewire position with the grasper. C) A well-lubricated jejunal extension tube is advanced over the guidewire and through the gastrostomy tube into the stomach and beyond the pylorus. D) Fluoroscopic image showing distal advancement of the jejunal extension tube made possible by forward traction with a rat tooth forceps (arrow). E) Endoscopic view of the jejunal extension tube as it is gently pushed distally into the small bowel with forceps. F) Appropriate positioning of the jejunal extension tube using the over-the-wire technique.

At this point, the forceps are released from the wire and used to facilitate passage of the jejunal extension tube along the tract of the guidewire into the small bowel, if necessary (Figure 9D, E). Once the jejunal extension tube has been successfully placed into the small bowel, the guidewire may be completely withdrawn and removed. The final endoscopic view before releasing the wire should be direct passage of the feeding tube down through the pylorus without a loop formed in the stomach (Figure 9F).

While the over-the-guidewire technique may seem more straightforward and simplistic compared to the through-the-snare technique, it can be a more tiring and frustrating process because of the potential for tube displacement and/or loop formation within the stomach. Poor placement is generally indicated by formation of a loop which arches towards the fundus of the stomach. If the tube is not completely withdrawn as this occurs and insertion reattempted, the natural tendency of this loop is to promote proximal displacement of the tube back into the stomach. Fluoroscopy can be very helpful to guide advancement of the jejunal extension tube over the guidewire and detect loop formation if it occurs. Use of an air retention valve as previously described can help maintain air insufflation and visualization while endoscopically advancing the tube into the small bowel.

ENDOCLIP TECHNIQUE

This technique relies on several of the principles outlined above in the over-the guidewire technique, namely the use of an endoscopy accessory being held distally in the small bowel while the endoscope is functioning in the body of the stomach. Withdraw of the accessory

after the tube has been successfully positioned creates minimal drag on the jejunal extension at the level of the pylorus which reduces the risk of retrograde tube migration.

Through an established PEG, a jejunal extension containing a suture loop is passed (Figure 10A). Many commercially available kits come with a suture pre-loaded, but this can be added to almost any jejunal extension. The suture loop is grasped with an endoscopic clip which functions as a grasper. The clip is withdrawn into the endoscope to prevent inadvertent mucosal damage and the endoscope is advanced to the desired level in the small bowel. The clip is advanced out of the working channel of the scope, and is deployed, affixing the suture to the mucosa (Figure 10B). Additional clips can be added as desired by the endoscopist. The final clip is positioned and closed but not fired (Figure 10C). As described above, the clip is held distally in the small bowel as the endoscope is withdrawn over the accessory shaft and back into the stomach (Figure 10D). Fluoroscopy can be utilized to aid in this maneuver and to confirm that the tube remains in the desired position. The clip is fired, and the instrument shaft is withdrawn into the endoscope under direct visualization of the pylorus.

Figure 10. Endoclip technique for jejunal extension tube placement. A) A jejunal extension tube with suture loop is advanced through the PEG and grasped with an endoclip. B) After the endoscope has passed deep into the small bowel, the clip is used to secure the suture loop to the mucosa. C) An additional clip is used to grasp the mucosa, but is not fired, as the scope is withdrawn into the stomach. D) Endoscopic view of the pylorus demonstrating the jejunal extension (superior) and endoclip (inferior) immediately prior to withdrawal of the accessory.

TRANS-PERCUTANEOUS ENDOSCOPIC GASTROSTOMY TECHNIQUE

At our institution, the trans-PEG technique is reserved for patients who have already undergone PEG tube placement during a separate procedure and therefore have a mature gastrostomy (typically at least 2-3 weeks old). Additionally, we recommend a single-piece PEGJ for patients who have required repeated endoscopic procedures to replace their jejunal extension tubes for various reasons, the most common including tube malfunction from clogging or retrograde migration into the stomach.

Figure 11. Trans-percutaneous endoscopic gastrostomy technique for PEGJ placement. A) A small caliber endoscope is passed percutaneously through a mature gastrostomy tract, beyond the stomach, and into the small bowel. A guidewire is then advanced beyond the distal tip of the endoscope and into the small bowel. B) Endoscopic view showing advancement of a stiff 0.035 guidewire through a gastrostomy tract. C) A lubricated single-piece PEGJ device is passed over the guidewire and into the small bowel. D) Endoscopic view of tube advancement over the wire and across the pylorus. E) Endoscopic view demonstrating adequate positioning of the PEGJ in the distal body of the stomach with the jejunal extension arching towards the pylorus. The internal retention balloon is filled with saline to secure the PEGJ in place against the wall of the stomach.

This technique is simple and involves passing a small caliber endoscope percutaneously through a mature gastrostomy tract into the stomach, through the pylorus, and into the small bowel. Our preference is to use an ultrathin endoscope with a 5-6 mm outer diameter and a working channel capable of accommodating a stiff 0.035-inch guidewire. In some cases, the gastrostomy tract may need to be carefully dilated to facilitate passage of the endoscope and instruments. Once the maximum depth of insertion of the endoscope has been reached, a stiff, long guidewire is passed either endoscopically or under fluoroscopic guidance through the working channel of the endoscope and into the small bowel, ideally beyond the ligament of Treitz (Figure 11A). The endoscope is then withdrawn slowly to the exterior of the patient and off of the wire (Figure 11B). Then a single-piece PEGJ is passed over the wire and directed into the small bowel (Figure 11C, D). The guidewire is subsequently removed. Similar to the previously described techniques for jejunal extension tube placement, avoiding loop formation in the stomach is critical. Once appropriate positioning of the PEGJ has been confirmed, the internal retention balloon is filled to capacity with saline to secure the device in place and tube feeds can be immediately delivered (Figure 11E).

POST-PEGJ CARE AND COMPLICATIONS

Management principles are generally similar for most patients who have undergone percutaneous endoscopic deep enteral access procedures. Patients are typically observed for 4

hours after initial PEG with jejunal extension tube placement, after which enteral feeds may be started if there are no contraindications. Patients undergoing PEG to PEGJ conversion who already have a mature gastrostomy tract can often be administered tube feeds immediately. For patients with significant gastric outlet obstruction type symptoms, it is important to maintain aspiration precautions before and after jejunal extension tube placement, especially when enteral feeds are initiated. If nausea, abdominal pain, and/or significant vomiting persist, the G-tube can be placed to gravity with the output closely monitored. When administering feedings, all enteric medications and tube feeds should be given via the jejunal port and followed with a flush of least 15 mL of saline or sterile water. It is critically important that only liquids are given through the jejunal port. Administration of pills or crushed pill fragments will undoubtedly lead to clogging of the tube and the potential need for repeat procedures for tube replacement.

Other post-procedure instructions include those common to patients who have undergone PEG tube insertion. The gastrostomy site should be kept clean with mild soap and water for the first 7 to 10 days after placement. Use of hydrogen peroxide should be avoided during that timeframe as it can irritate the skin and contribute to stomal leaks. Occlusive dressings at the enteric site should also be avoided as they can lead to skin maceration and breakdown. We do not routinely apply a dressing to the enteric site after placement. However, if a dressing is applied, it should be placed over rather than under the external bumper, and a cut dry sponge is preferable. To prevent buried bumper syndrome, the external bumper of the gastrostomy or PEGJ should be positioned so that the tube is moveable and can be pushed in and out of the tract at least 1-2 cm. We customarily have patients return in one to two weeks to evaluate the enteral access site and confirm that the external tube and adapters remain intact and are appropriately functioning.

Complications of PEGJ tubes include those described elsewhere for PEG tube placement as well as those unique to insertion of the jejunal extension including tube migration into the stomach and tube dysfunction from clogging, kinking, or occlusion. One note to be made is that while free intra-peritoneal air likely occurs universally after PEG, if the placement of the jejunal extension requires significantly more endoscopy time, the amount of air that leaks around the newly created gastrotomy can be significant and may be more likely to be detected clinically or radiographically. Use of carbon dioxide during PEGJ placement can increase the rate at which the intra-abdominal air is reabsorbed.

Retrograde dislodgement of the jejunal extension tube is common and has been reported in up to 33% of cases [18]. This is often a source of frustration for patients and providers and usually results in repeated procedures to obtain proper positioning. Occlusion of the smaller caliber 8-12 Fr jejunal extension tubes can also be problematic with rates as high as 35% when crushed medications are administered through the jejunal port [19]. The functional longevity of the jejunal arm varies in each clinical situation, but we typically have patients return for tube changes every 3-6 months or as needed.

EDITOR'S COMMENT

As Drs Gaffney and Moyer point out in this chapter, the simplistic concept of placing the distal end of a PEGJ tube beyond the pylorus and ensuring that it remains there is often not so

simplistic in its execution. The fact that there are multiple viable techniques to accomplish this task speaks to the true complexity of this endeavor and to the ingenuity of endoscopists who have been faced with the problem of a tube that simply will not go or will not stay post-pyloric. Experience, training and patience are a must when attempting PEGJ. (EMP).

Chapter 133

ALTERNATIVE GASTRIC ACCESS METHODS: SLiC AND PTEG

Adrian B. Dobrowolsky, MD and Bipan Chand*, MD

Loyola Univeristy Medical Center, Marywood, IL, US

INTRODUCTION

While percutaneous endoscopic gastrostomy (PEG) placement is generally easy to perform with an overall low morbidity to patients, not all patients have favorable anatomy to allow for its use. For example, those with large nearly-obstructing oropharyngeal masses bring challenges that may be difficult to overcome with many surgeons opting for an open approach instead of endoscopically placed feeding catheters. Additionally, seeding of the abdominal wall has been reported from PEG placement in those with head and neck cancers. Alternatively, patients with ascites secondary to hepatic failure or malignancy are at a higher risk and the dangers of potentially developing infected ascites and its sequelae greatly outweigh the benefits in many. In this chapter we will focus on two alternative methods of enteral access; the Sabnis, Liu and Chand (SLiC) technique and the percutaneous transesophageal gastrostomy (PTEG) technique.

SLiC Indications

The SLiC technique was first described in 2005 by Sabnis et al. [1]. In this method, a gastroscope is used to visualize a dilating laparoscopic trocar enter the stomach. A Malecot catheter is then placed through the trocar and secured. Reasons to utilize this technique include strictures of the aerodigestive tract from radiation, inflammation, or obstructive cancers that may preclude a large mushroom tipped catheter from traversing the lesion in a traditional PEG procedure. Because this method permits the immediate placement of a 20 French (Fr) tube, the technique is less prone to clogging by medication and tube feed

* Corresponding Author's Email: bchand@lumc.edu.

administration associated with radiologically placed 12 Fr gastrostomy tubes and does not require the tube to be upsized at a subsequent clinical encounter [1].

In a prospective review by Ellrichmann et al. 26 patients with head and neck cancers, 13 with esophageal cancers, and one with esophageal invasion by a lung cancer underwent traditional pull-type PEG and cytologic analysis of tubing and incision sites. They demonstrated malignant cells in 22.5% of tube samples and a metastatic seeding rate of 9.4% in those whose PEG sites were tested again at a later date [2]. Metastatic seeding of the PEG sites has been well documented in case reports with an overall prevalence of about 1-2 cases per year, most commonly from squamous cell cancers [2, 3]. The SLiC method eliminates pulling the tube through the location of any oral-pharyngeal-esophageal cancer.

SLiC Technique

This method requires the following equipment: gastroscope, local anesthetic, number 11 blade scalpel, Step™ insufflation needle and 7-8 mm MiniStep™ trocar (Medtronic, USA) 20 Fr Malecot catheter, stiff metal stylet, nonabsorbable suture (Figure 1). The Malecot is prepared by placing the stylet inside and elongating the mushroom tip for easy placement. A slim pediatric (6 mm) or ultra-slim (<5 mm) gastroscope (possibly passed transnasal) may be necessary in order to traverse a large or partly-obstructing mass lesion or stricture (Figure 2).

Figure 1. Instrumentation for SLiC procedure. A) Access Needle B) 7-8 mm trocar sleeve C) Dilator D) 7/8 MiniStep™ cannula E) Stylet F) 20Fr Malecot catheter.

Procedure specifics are adapted from Sabnis et al. [1]. The patient is placed supine on the procedure table and the upper abdomen prepped and draped in the usual sterile fashion. Under direct visualization the gastroscope is passed into the stomach and then the stomach is insufflated. Using transillumination, gastric indentation by a second individual and a safe-tract technique, the location of gastrostomy is safely confirmed. Local anesthetic is then used to infiltrate the site and a 7 mm skin incision is made using the 11-blade scalpel. The trocar sleeve and access needle are quickly driven through the incision, abdominal wall, and stomach under visualization with the gastroscope (Figure 3). A swift, controlled motion is necessary here because the outer diameter of the dilating sleeve is larger than that of the 14 gauge Veress-type access needle. The access needle is subsequently removed and the 7-8 mm

dilator along with its cannula is then passed through the sleeve to dilate the tract and place the cannula. The dilator is then removed leaving the sleeve and cannula in place (Figure 4). The one way valve on the laparoscopic trocar prevents air leak, allowing gastric inflation to be maintained. The Malecot catheter is then placed through the trocar approximately 5-6 cm into the gastric lumen using the stylet and lubricant (Figure 5). The stylet is removed. The Step™ trocar is then carefully withdrawn over the tube leaving the Malecot in place (Figure 6). The Malecot is sutured to the skin. The Malecot tip can be directed into the fundus if decompression of the stomach is the desired affect.

Figure 4. The dilator is removed, leaving the cannula within the sleeve.

Figure 5. The 20Fr Malecot catheter is prepared with a metal stylet inside its tip and inserted into the stomach through the cannula. The stylet is then removed.

Figure 6. The cannula is removed while holding the Malecot catheter in place.

PTEG Indications

In 1994, Oishi et al in Japan developed the percutaneous transesophageal gastrostomy (PTEG) technique as a novel way to provide a gastric tube for decompression or feeding by means of direct access to the esophagus [4]. In patients with hostile abdominal cavities from bulky malignancies, adhesive disease, or ascites secondary to hepatic dysfunction or intraabdominal neoplasm, PTEG is an alternative to the traditional transabdominal gastrostomy tube. During PEG placement, patients with ascites are at a much higher risk of secondary bacterial contamination and subsequent peritonitis from poor apposition of the gastric and abdominal walls from the ascites or malnutrition leading to poor tract formation [5]. Like the nasogastric tube, PTEG is suitable for gastric decompression as the tube lays in the most dependent portion of the stomach. This is in contrast to the PEG tube that lies anteriorly and is only able to decompress the stomach when it is filled to its most anterior portion providing a far inferior decompression of the stomach. Also, inadvertent removal of a PEG may necessitate laparotomy when the tract has not matured whereas, due to its location, inadvertent removal of a PTEG is less concerning as the site will likely heal without major consequence if not expeditiously replaced with another catheter.

PTEG Technique

This method requires the following equipment: a rupture free balloon (RFB) and catheter, straight and angled guidewires, contrast, needle with sheath, 16 Fr dilator with peel-away sheath, PTEG catheter, scalpel, nylon suture, ultrasound, and fluoroscopy (Figure 7). The

current “kit” is not readily available in the United States. However, the majority of the equipment can be pieced together from existing hospital inventory. The RFB balloon is composed of chloroethylene, a material that permits it to not burst when punctured with a needle and be readily visible on ultrasound.

Procedure specifics are adapted from Oishi et al. and Mackey et al. [4, 6]. The patient is placed supine on the procedure table and sedated. A straight guidewire is passed transnasal into the esophagus and confirmed on fluoroscopy. Using Seldinger technique, the RFB is placed over the wire and advanced distal to the cricopharyngeus muscle where it is filled with dilute contrast media. When confirmed in the esophagus, it is advanced to just above the clavicles and using an ultrasound probe on the patients left neck, the common carotid artery, internal jugular vein, and thyroid are visualized. Due to the distention of the RFB, the trachea and thyroid become displaced medially and the vessels laterally. At the proposed entry site, local anesthetic is used and using ultrasound guidance, the needle and its sheath are used to puncture into the RFB (Figure 8). Confirmation of successful RFB puncture is established by resistance when the RFB is punctured, visualization of the tip of the needle entering the RFB under ultrasound guidance, and visualized contrast media outside the balloon into the sheath upon withdrawing the needle on fluoroscopy (Figure 9). When confirmed, the needle is carefully removed while holding its sheath within the RFB. Then, an angled guidewire is introduced through the sheath into the RFB. Under fluoroscopic guidance, both the cervical guidewire and the RFB are advanced approximately 20 cm distally where the guidewire will fall out of the RFB but remain in the esophagus (Figure 10).

The RFB and nasal wire are removed leaving only the trans-cervical guidewire. At the skin level, a 1 cm incision is made and the 16 Fr dilator and peel-away sheath are inserted over the guidewire under fluoroscopy using a twisting motion (Figure 11). Once fully inserted, the guidewire and dilator are removed leaving the peel-away sheath. The PTEG catheter is then introduced into the sheath and advanced into the stomach with its location confirmed with injection of contrast under fluoroscopy. The sheath is then peeled away and the PTEG tube is secured with nylon suture (Figure 12).

Figure 12. Percutaneous transesophageal gastrostomy site after the tube is secured and dressed.

PTEG Limitations

Not all patients are suitable for PTEG placement. Specifically, those patients with head and neck lesions, coagulopathy, and right recurrent laryngeal nerve paralysis are contraindicated to undergo PTEG placement [6]. PTEG carries an overall 23.5% risk of minor complications seminal to PEG placement, including tube dislodgement, blockage, leakage, bleeding and wound infections [4]. Procedural limitations to performing successful PTEG placement are the ability to interpret not only ultrasonography, but also fluoroscopy [6].

CONCLUSION

While most patients are suitable for PEG placement, special situations call for alternative therapies to provide similar results. The SLiC technique is useful in the setting of aerodigestive obstruction that makes a traditional PEG difficult or impossible to place without undue trauma to the offending lesion. Also, this prevents the small possibility of PEG site seeding of malignant cells when the pull or push PEG mechanism is utilized. PTEG provides a means for feeding or gastric decompression in patients with advanced malignancies or ascites from secondary causes which preclude them from other transabdominal approaches.

EDITOR'S COMMENT

The techniques outlined here not only require specialized equipment, but they required advanced surgical and/or imaging interpretation capabilities. Despite these two limitations, they remain very useful methods for those patients who are not candidates for more traditional methods of gastric access. Practitioners who can master these adjunct PEG methods are capable of providing advanced gastric access to patients who might otherwise be deemed not candidates for a more permanent gastrostomy tube (EMP).

Chapter 134

‘ASSISTED’ PEG PLACEMENT

Salvatore Docimo, Jr., DO and Eric M. Pauli*, MD

Penn State Hershey Medical Center, Hershey, PA, US

INTRODUCTION

As outlined in previous chapters, percutaneous endoscopic gastrostomy (PEG) placement requires anatomical landmarks and technical maneuvers (such as gastroscopic transillumination and external manual palpation of the abdominal wall with visualized confirmation endoscopically) in order to ensure safe and appropriate placement [1]. However, certain patient characteristics (e.g., difficulty passing a gastroscope, previous gastric surgery, failure of transillumination of the abdominal wall, colon interposition) make PEG placement both difficult and potentially unsafe. In many of these scenarios, laparoscopic or open gastrostomy tube placement may be preferable. However, the use of upper endoscopy in conjunction with advanced imaging such as computerized tomography (CT) scans, fluoroscopy, or ultrasound can also help overcome the difficulties outlined above. Simultaneous upper and lower endoscopy has also been utilized to ensure safe PEG placement. This chapter focuses on the use of an adjunct modality (upper endoscopy plus a secondary modality) to assist in the performance of PEG.

LAPAROSCOPIC-ASSISTED PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Laparoscopic-assisted PEG (LA-PEG) is likely the most common utilized method of multi-modal therapy and it represents the fusion of two minimally invasive techniques into one laparo-endoscopic procedure. Raaf et al. first described LA-PEG in 1993 in a patient requiring a gastrostomy tube where the colon lay on the greater curvature of the stomach [2]. This technique can be utilized in patients where viscera (left lateral segment of the liver,

* Corresponding Author's Email: epauli@hmc.psu.edu.

colon, small bowel) are known to overlay the stomach and in patients where there is absence of transillumination of the abdominal wall and/or a 'safe-tract' during a standard PEG. In a series published by Hermanowicz et al. twelve patients underwent laparoscopic assisted PEG placement. In a supine position, a 5-mm trocar was inserted under the umbilicus using Hasson's open technique and pneumoperitoneum was obtained. A gastroscope was then introduced and a gastrostomy site was selected under laparoscopic and endoscopic visualization. The PEG was completed utilizing the 'pull' technique. All twelve patients successfully received a PEG with no major intraoperative complications [3].

Typically, laparoscopic-assisted PEG requires the placement of just one 5-mm trocar for insertion of a laparoscope which is utilized for selection of a safe gastrostomy site. A second working port can be placed if needed for retraction of intraperitoneal viscera in order to create a clear gastrostomy site (Figure 1). Once laparoscopic visualization has confirmed that there is a safe location for the gastrostomy with no intervening abdominal viscera, the PEG can be completed using pull, push or introducer methods based on surgeon preference (Figure 2). As outlined in Chapter 9, the procedure can be conducted with additional working ports and laparoscopic suturing methods but at this point the procedure essentially becomes a laparoscopic gastrostomy tube with endoscopic guidance.

FLUOROSCOPY-ASSISTED PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

While fluoroscopy is routinely utilized by therapeutic endoscopists for more complex interventions (e.g., bilio-pancreatic procedures, management of leaks and fistulae) the use of fluoroscopy to assist in PEG placement (FA-PEG) is not common. Grant utilized intraoperative fluoroscopy in only 0.33% (2/598) of patients undergoing PEG [4]. Fluoroscopically placed gastrostomy tubes (without the use of endoscopy) can be safely performed with the introducer method, although the initial tube size is generally smaller than with other methods of PEG [5]. There are several circumstances in which the combined use of endoscopy and fluoroscopy for PEG placement are advisable.

We occasionally use fluoroscopy in patients who have been deemed to be not candidates for PEG based on pre-operative imaging studies, or who have failed a previous attempt at PEG by another provider (typically due to no transillumination or inability to find a 'safe-tract') (Figure 3). FA-PEG may also be beneficial in patients that have medical-surgical hardware (e.g., ventricular-peritoneal (VP) shunt, diaphragm or gastric pacemaker, temporary cardiac pacemaker wires, ventricular assist device drive lines) that traverses the epigastrium [4]. In these circumstances the real-time imaging allows the endoscopist to avoid puncture of the device with the PEG and to place the PEG remotely from the device to reduce the risk of post-procedure infection (Figure 4).

We routinely utilize fluoroscopy during PEG when we are also performing simultaneous colonoscopy (see Colonoscopic-Assisted Percutaneous Endoscopic Gastrostomy section below) as an adjunct to ensure adequate colonic decompression prior to performing a 'safe-tract' maneuver. Similarly, as better outlined in Chapter 15, fluoroscopy during hiatal hernia reduction and double-PEG gastropexy is a useful adjunct to ensure the safety of the procedure.

Figure 1. Laparoscopic-assisted PEG in a patient with colon distension that prohibited a 'safe-tract' to be found during the initial PEG attempt. A 5 mm trocar was placed at the umbilicus for visualization. A second 5 mm left sided working port was necessary to permit retraction of the transverse colon that could not be sufficiently moved by reverse Trendelenburg position. Gastrointestinal T-anchors were subsequently placed and an introducer PEG method was used to place a primary button gastrostomy tube under endoscopic visualization.

Figure 2. Laparoscopic view of a gastrostomy tube safely traversing the abdominal and gastric wall during a laparoscopic-assisted PEG.

COMPUTED TOMOGRAPHY-ASSISTED PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Although PEG has become more widely used than percutaneous radiologic gastrostomy (PRG), PRG remains a better option in some circumstances including; inability to transilluminate endoscopically, obstructing head and neck cancer (HNC) or esophageal cancers, obesity, previous gastric surgery, or patients with a hostile abdomen, either due to malignancy or severe adhesive disease secondary to multiple surgeries. During the procedure, the stomach is often inflated via a nasogastric tube and a CT scan is performed in order to ascertain a clear path to the stomach, ideally, one in which the stomach is in close proximity

to the anterior abdominal wall without any anterior organs in between (Figure 5). This includes radiologic guided insertion of intercostal pigtail tubes. Utilizing CT imaging, an introducer needle is visualized entering the air filled stomach. A guidewire is then placed. At this point, dilation and placement of the gastrostomy tube can occur in either the radiology or endoscopy suite.

Figure 3. Imaging from a patient who had failed routine PEG tube placement due to inability to find a 'safe-tract.' A) The patient was deemed not a candidate for a CT-guided gastrostomy based on the distended colon overlying the stomach (arrowhead). B) FA-PEG was performed which safely identified a location below the costal margin with no intervening colon (at instrument tip) where a PEG tube was ultimately placed utilizing a routine 'pull' method.

Figure 4. Image obtained during FA-PEG on a patient with a 4-day-old VP shunt that traverses the epigastrium (arrowheads). A finder needle (arrow) is used to mark the planned location for a 'safe-tract' attempt at a location remote from the shunt. The endoscope can be seen in the body of the stomach providing insufflation.

Figure 5. CT-guided access to the stomach in a patient with ovarian carcinomatosis and bowel obstruction symptoms who failed PEG due to the inability to distend the stomach.

Computed Tomography-Assisted Percutaneous Endoscopic Gastrostomy (CTA-PEG) was first described by Vogt et al. in 1996. In 7 of 124 patients, PEG was not possible due to failure to transilluminate the abdominal wall; 3 from prior Billroth gastrectomy, 2 from hepatosplenomegaly, and 1 each from obesity and Chilaiditi syndrome (colonic interposition). Utilizing real-time CT guidance, they were successful in PEG placement in 6 of the 7 patients with no major complications [6].

Spelsberg et al. published a series of patients undergoing CT guidance with or without endoscopy for the placement of gastrostomy tubes. Gastrostomy was successful in 89 of 101 patients with CTA-PEG being employed in 61 of the 89. Forty-five of the 61 patients (74%) were noted to have previously unknown pathological findings and twenty-nine (48%) were found to have pathological findings, such as peptic ulcer disease or suspicious tumor manifestations, which altered the management plan [7].

There are three methods by which CTA-PEG can occur; immediate, same-day rendezvous or delayed rendezvous. In immediate CTA-PEG, both the endoscopy team and radiology team are present in the interventional radiology (IR) suite (Figure 6). Following the administration of anesthesia, an upper endoscopy is performed with the patient on the CT table. Standard maneuvers to localize the PEG site (transillumination, 'safe-tract') are augmented by the use of real-time CT images as well as the placement of radiopaque skin markers (Figure 6E). Once a location is identified, standard PEG methods (pull, push or introducer) can be performed. This procedure has the advantage of permitting a large caliber (20-24 Fr) gastrostomy to be placed in a safe and immediate fashion, but it requires careful coordination of 2-3 (radiology, endoscopy and possible anesthesiology) services in a limited procedure space.

Same-day rendezvous CTA-PEG begins as with a percutaneous radiologic gastric access. CT images are obtained and a safe location for the tube is identified. Needle and wire access to the stomach are obtained. The wire is robustly-secured to the skin, and the patient is transported to an endoscopy or procedural suite where endoscopy is used to retrieve the wire

per os. A PEG is completed using standard methods. While there is potential for wire dislodgement during transport, this procedure has the advantage of permitting both involved services (radiology and endoscopy) to function independently of one another and to both perform their portion of the procedure in familiar, well-equipped environments.

Figure 6. Immediate CT-Assisted PEG in a patient with obstructive symptoms from a small bowel motility disorder. A) Upper GI study demonstrates abnormal gastric positioning in the left upper quadrant (entirely subcostal) and severe small bowel dilation. B) Scout CT image demonstrates similar bowel distension. C) On-table upper endoscopy is performed in the IR suite. D) Repeat CT scan shows the endoscopic within the body of the stomach. E) Radiopaque skin marker (arrowhead) identifies the proposed site for PEG. F) Completed 'pull' method PEG position is confirmed via completion CT.

Delayed rendezvous CTA-PEG begins as with a percutaneous radiologic gastrostomy. CT images are obtained and a safe location for the tube is identified. Needle and wire access to the stomach are obtained and a small caliber pigtail catheter is placed over the wire into the lumen of the stomach. Several weeks after this procedure (i.e., in a delayed fashion), endoscopy is used to rendezvous with the well-established drain tract and replace the small caliber tube with a larger caliber standard PEG gastrostomy (Figure 7).

Figure 7. Delayed CT-Assisted PEG for decompression of malignant bowel obstruction. A) CT guided pigtail tube is placed through the intercostal space due to carcinomatosis limiting safe PEG placement. B) Several weeks after placement, endoscopy is performed to identify the intercostal pigtail tube in the lumen of the stomach. C) The small caliber pigtail is exchanged for a larger caliber standard PEG tube for more effective gastric decompression.

It should be noted that while both utilize CT and endoscopy technology, CTA-PEG differs from Endoscopic Ultrasound Assisted/Computed Tomography-Guided enteral access described in detail in Chapter 13. In CTA-PEG, the gastrostomy placement is primarily being performed endoscopically with CT providing imaging data to assure safety, or providing a wire/tube over which the PEG can be performed. During Endoscopic Ultrasound Assisted/Computed Tomography-guided gastrostomy, endoscopy techniques are used to assist in gastric insufflation for what is ultimately a percutaneous radiologic gastrostomy.

ULTRASOUND-ASSISTED PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Similar to CT and fluoroscopy, ultrasound (US) can be utilized as a sole or adjunct modality for gastrostomy placement. Hoffer first described the use of US alone to perform 17 percutaneous gastrostomies in patients warranting enteral access [8]. Klek et al. utilized a thin nasogastric tube passed into the stomach to fill it with 1000 ml of water. US was then performed with a 7.5 MHz probe. The stomach was located and contact between abdominal and gastric walls was confirmed. An additional 500 ml water bolus was used to improve contact between the gastric and abdominal walls. Gastropexy sutures were then placed, the abdominal wall was punctured and a gastrostomy tube was passed. Once water began to flow through the gastrostomy tube, placement in the stomach lumen was confirmed and the balloon was filled with 10 ml of water. Correct placement of the gastrostomy tube in the stomach could then be confirmed with ultrasonography. Eleven patients obtained successful placement of a gastrostomy tube via this method described. Two patients (18%) experienced minor complications which included postoperative pain requiring removal of one to the gastropexy sutures after 3 days and re-insertion of a new balloon catheter [9].

Ultrasound-Assisted Percutaneous Endoscopic Gastrostomy (USA-PEG) has been described in the literature. In circumstances where transillumination has failed, US can be utilized to identify a safe location for the gastrostomy. In 1993, Vargo described the use of US to assist endoscopic gastrostomy placement in a patient with ovarian carcinomatosis. Transcutaneous US assisted in localizing the site for PEG, allowing a tract to be identified that avoided abdominal viscera and metastatic foci [10]. In a larger series, Schlottmann et al. successfully performed USA-PEG in 14/15 patients who failed to transilluminate during endoscopy alone thereby eliminating the need for a surgical gastrostomy in 93% of their patients [11]. USA-PEG has also been performed successfully on patients with abdominal wall varices, with US images being utilized to help identify a safe location for gastrostomy placement around the dilated veins [12].

COLONOSCOPY-ASSISTED PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

In order to safely perform a PEG, transillumination of the abdominal wall via the gastroscope is necessary. One cause of failed transillumination is the interposition of the colon between the stomach and abdominal wall. Penetration of the colon, with development

of a gastro-colo-cutaneous fistula, is a complication of failure to recognize overlying colon. Lax mesentery, motility disorders, and previous abdominal surgery can predispose other segments of the colon to lay anterior to the stomach. Fortunately, misplacement of a PEG tube into the colon is a rare occurrence. Over a five year period, only six cases out of 2384 PEGs resulted in colonic injury and formation of colocutaneous fistulae [13].

Attempts at minimizing injury to the colon during a PEG are focused upon mobilizing the colon away from the anterior stomach wall. Generally, gastric insufflation and reverse Trendelenburg positioning are sufficient to move the colon to a safe position, but in situations where the colon still prevents direct access to the stomach, a colonoscopy-assisted percutaneous endoscopic gastrostomy can be performed. The patient is placed in a supine, frog-leg (or low lithotomy) position to permit simultaneous access to both mouth and anus for endoscopy. Our preference is to perform the procedures in an operative suite under general anesthesia.

Figure 8. Colonoscopic-assisted PEG. A) Distended transverse and sigmoid colon overlay the stomach (outlined by post-pyloric feeding tube) in a patient with a colonic motility disorder post-operative day 7 after a blowhole transverse colostomy. B) CT scan demonstrating the body of the stomach (white arrow) and interposed colon. C) Despite decompression of the transverse colon via the stoma, the sigmoid colon is still seen anterior to the stomach and gastroscope (black arrow). D) Decompression of the sigmoid colon is performed by passing the colonoscope per rectum. E) Endoscopic view from the stomach demonstrates the colonoscopic light source within the sigmoid colon. F) Fluoroscopy is used to localize a safe location to place the PEG within the distended gastric body (outlined in red).

Figure 9. Colonoscopic-assisted PEG. A colonoscope (white arrow) is being use to manually distract a contrast filled transverse colon to permit an upper endoscope (black arrow) to place a gastrostomy tube in the body of the stomach in a safe location (arrowheads).

The use of the colonoscope (simultaneously with upper endoscopy and generally fluoroscopy) has several rolls. In cases of colonic distension, the colonoscope can be used to decompress the colon and permit a safe window for PEG (Figure 8) [14]. If simple decompression alone is insufficient, standard colonoscopy maneuvers can be utilized to manually shift the position of the colon under fluoroscopic guidance (Figure 9) [15, 16]. Once the guidewire access has been placed, it is our preference to visually inspect the colon lumen for any endoscopic evidence of injury prior to completing the gastrostomy and dilating the tract with a 20 Fr gastrostomy tube (Figure 10).

Figure 10. Gastroscope view of the retrieval of a PEG guidewire with a snare and simultaneous colonoscopic view (inset) demonstrating no evidence of wire perforation of the colon.

Figure 11. Room setup for colonoscopic-assisted PEG. Left image taken from the head of bed (HOB), right image represents an overhead view.

While safely reported in the literature, colonoscopic-assisted PEG is a highly complex procedure requiring two skilled endoscopists and an elaborate room set-up (Figure 11). The endoscopists must be able to interpret simultaneous upper and lower endoscopy images as well as fluoroscopy. It should only be performed by practitioners skilled in all three modalities and only after careful patient selection and appropriate pre-operative counseling.

CONCLUSION

These 'assist' modalities for PEG have broadened its reach to include even those who would otherwise require a surgical gastrostomy. While demonstrated to be safe, they all require high levels of procedural skill, adaptability and coordination of teams and should be approached with caution and careful consideration.

EDITOR'S COMMENT

This chapter reviews the many techniques needed to gain enteral access in patients who are unable to undergo routine endoscopic placement. The endoscopist must be aware of the roles of the surgeon and radiologist in assuring safe placement of feeding tubes. A collaborative, multidisciplinary approach will allow for the most efficient and safe performance of enteral access (JMM).

Chapter 135

PEG AND PEJ IN THE POST-BARIATRIC SURGERY PATIENT

Ryan M. Juza and Ann M. Rogers*

Penn State Hershey Medical Center, Hershey, PA, US

INTRODUCTION

Weight loss surgery comprises one of the most common group of elective general surgical procedures performed in academic medical centers in the United States, with over 200,000 operations performed annually in the United States (US) alone [1, 2]. The two most common bariatric surgical operations performed in the US are vertical sleeve gastrectomy (VSG) and Roux-en-Y gastric bypass (RYGB) respectively [2, 3]. Roux-en-Y gastric bypass, for years the gold standard operation for obesity, was replaced in 2013 by VSG as the most frequently performed weight loss operation [4, 5]. Bariatric surgery is the most durable and effective treatment for severe obesity and demonstrates a significant improvement in obesity-related conditions such as Type II diabetes, hypertension, and heart disease [6-8]. While surgical outcomes are excellent, postoperative complications and other pathology may require the establishment of durable enteral access for the purpose of diagnosis and treatment [9-12].

Indications for durable enteral access in post-bariatric surgical patients include primary access for the treatment of postoperative complications such as refractory anastomotic strictures, recalcitrant nausea, chronic distention, dehydration, and failure to thrive. Secondary causes include providing access to the biliary tree for endoscopic therapy in RYGB patients [13]. Patients who have undergone a bariatric surgical procedure remain susceptible to the same disease states that may warrant enteral feeding access in the general population (intra-cranial pathology, neuromuscular disorders, traumatic injuries, etc.) and as such, endoscopists need to be familiar with methods of obtaining enteral feeding access in post-bariatric surgery patients.

Established enteric access can be used for decompression, delivery of medications or nutrition, and as an access point for endoluminal therapies. Open and laparoscopic surgery

* Corresponding Author's Email: arogers@hmc.psu.edu.

remain the pillars of clinical management for these conditions but often previous surgeries, postoperative adhesions, and the need for general anesthesia make these options less desirable. Endoscopy is already widely used for diagnostic and therapeutic purposes in bariatric patients. With the addition of advanced instrumentation and balloon-assisted endoscopy (BAE), several methods of endoscopically establishing enteral access in post-bariatric patients are now described in the literature and widely used in practice [14]. In this chapter we describe options for establishing enteral access in the post-bariatric surgical patient based on the postoperative anatomy and the medical indication for placement.

TECHNIQUES: PERCUTANEOUS ENDOSCOPIC GASTROSTOMY (PEG) TUBE PLACEMENT

Roux-en-Y Gastric Bypass (RYGB) Excluded Stomach

Accessing the excluded stomach following RYGB is often challenging because of postoperative adhesions, altered surgical anatomy, and the native location of the transverse colon. Previously, some advocated creating a prophylactic surgical gastrostomy in the bypassed stomach at the time of surgery for challenging cases to aide in access should complications arise postoperatively [15]. This practice has fallen out of favor because of the low complication rates of laparoscopic bariatric surgery as well the increasing number of options available to gain percutaneous access to the excluded stomach. Indications for durable tube access through the bypassed stomach following RYGB include chronic distention of this viscus and in the instance of biliary pathology to provide access to the biliary tree for therapies such as endoscopic retrograde cholangiopancreatography (ERCP). Other indications include GI bleeding, anemia, and abnormal imaging suggestive of gastric neoplasm. When open or laparoscopically placed gastric access is not desirable, endoscopically placed and radiographically-guided access are suitable options.

Balloon-Assisted Endoscopy (BAE)

The combined length of the alimentary and biliopancreatic limbs following RYGB makes endoscopic access to the bypassed stomach challenging. BAE was first described by Yamamoto et al. in 2001 as a method of providing deep endoscopic access to the entire small bowel [16]. BAE has since been adapted and utilized in post-bariatric surgical patients to provide retrograde endoscopic access to the bypassed foregut structures for diagnostic and therapeutic uses [17-20]. In BAE, the endoscope is introduced *per os* and advanced into the gastric pouch and through the gastrojejunal anastomosis. Typically the entire alimentary limb can be traversed by directly advancing the endoscope until the confluence of the alimentary and biliopancreatic limbs is reached. At this point, the distance and anatomy often prevent further forward motion of the endoscope. From the jejunojejunostomy, a balloon attached to the end of the endoscope can be advanced and inflated to contact the bowel wall. The friction between the balloon and the bowel wall is used to pull the endoscope forward a short distance and the steps repeated. This push-and-pull technique can be used to telescope the bowel over the endoscope as it advances, to shorten the distance between the mouth and bypassed stomach. The BAE endoscopy is continued retrograde up the biliopancreatic limb until the

excluded stomach is reached. Once the pylorus is intubated, the excluded stomach is insufflated to create apposition between the anterior gastric wall and the abdominal wall. With the remnant insufflated, options for tube placement include a Pull method (see Chapter 7) or an Introducer method (see Chapter 9) utilizing standard PEG kits. Fluoroscopy is a useful adjunct for both methods.

Figure 1. Introducer method of PEG via Balloon Assisted Endoscopy. A) Endoscope is inserted per-os, and then advanced to the remnant stomach using standard balloon enteroscopy maneuvers B) Following the identification of a safe tract for PEG, gastrointestinal T-anchors are placed into the remnant stomach for gastropexy. C) A guidewire is positioned centrally to the T-anchors and D) The tract is serially dilated to the desired diameter. E) Through a peel away sheath a balloon gastrostomy tube is introduced F) As the sheath is removed the balloon is inflated, securing the gastrostomy tube within the gastric lumen.

For the Ponsky-Gauderer “pull” technique, the endoscope is directed toward the anterior wall of the stomach and transillumination used for localization on the abdominal wall. The endoscope is left in place and a snare is advanced through the instrument channel. A hollow bore localizing needle is then passed transabdominally and escape of air bubbles through the needle confirms appropriate placement. Through the needle a looped wire is passed, and the snare is used to grasp and secure the wire. The endoscope and wire are drawn toward the pylorus. With the endoscope removed, the end of the snare is opened to release the wire. The appropriate sized PEG tube is secured to the wire and the endoscopic snare cinched to the

PEG bumper to permit the endoscopist to directly follow the gastrostomy tube back into the bypassed stomach [21]. The size of gastrostomy tube used is determined based on the pathology being treated. If the patient has chronic dilatation of the bypassed stomach, a small caliber (14F) gastrostomy tube can be placed to allow intermittent decompression.

If the patient requires access to permit endoscopic therapy of the biliary tree, a larger gastrostomy tube can be placed, or serially upsized once the tract is established, to accommodate a duodenoscope. In these situations, because of the complexity of reaching and subsequently placing the gastrostomy tube, we choose to pexy the stomach using gastrointestinal T-anchors to prevent disruption of the gastrostomy tract in the event of inadvertent tube dislodgement.

For the Russell “introducer” technique, the endoscope is directed toward the anterior wall of the stomach and transillumination used for localization on the abdominal wall (Figure 1A). A safe tract is established in a standard fashion and gastrointestinal T-anchors (typically 3-4) are placed surrounding the anticipated location for the gastrostomy (Figure 1B). With upward traction on the anchors, and under direct endoscopic visualization, a wire is positioned in the stomach (Figure 1C) and the gastrostomy tract is serially dilated over the wire to the desired size (Figure 1D). A peel away sheath (typically included as part of the last dilator) is positioned across the tract, and the tube is advanced intraluminally (Figure 1E). The peel away sheath is removed, the gastrostomy balloon is inflated (Figure 1F).

Despite advances in BAE, this technique remains challenging. Success rates in the literature range from 60-70% of cases and it is not practiced by all endoscopists because it carries a steep learning curve [17-19, 22]. BAE requires general endotracheal anesthesia and operative times to reach the excluded stomach can be 2-3 hours. Despite these challenges, BAE provides an option for endoscopically accessing the bypassed stomach for PEG.

Endoscopic Ultrasound Assisted/Computed Tomography-Guided Enteral Access

Computed Tomography (CT)-guided percutaneous enteral access have a high rate of success in post-RYGB surgical patients but are contraindicated when bowel is interposed or in the absence of a clear window into the lumen [23-27]. Endoscopic assistance for radiographically-placed enteral access is an alternative to open or laparoscopic surgical options when image guided (ultrasound, fluoroscopy, CT) percutaneous gastrostomy tube placement is unsuccessful in itself. As described in several small series, echoendoscopic-assistance for a radiographic guided gastrostomy tube placement is used in cases where a clear window cannot initially be seen [28-30]. In this technique an echoendoscope is passed *per os* into the gastric pouch and endoscopic ultrasound (EUS) used to identify the decompressed lumen of the adjacent bypassed stomach (Figure 2A). A large gauge biopsy needle is used to puncture through the gastric pouch and into the juxtaposed wall of the remnant stomach (Figure 2B). Contrast is injected and fluoroscopy is used to confirm accurate puncture of the viscus (Figure 2C). The remnant stomach is then insufflated through the needle to create apposition between the gastric body and the anterior abdominal wall (Figure 2D) thus facilitating radiographically-guided gastrostomy tube placement using a percutaneous introducer technique (Figure 2E and F). Successful EUS-assisted radiologic gastrostomy tube placement was accomplished in 10/11 patients in two small series [28-29]. This option provides a less-invasive treatment alternative to open or laparoscopic gastrostomy

tube placement when BAE is not feasible, but requires expertise in EUS as well as potential coordination of two teams (EUS team and radiology team).

Figure 2. Endoscopic Ultrasound (EUS) assisted access to the gastric remnant. A) The Echoendoscope is passed *per os* into the gastric pouch and ultrasound used to identify the decompressed lumen of the adjacent remnant stomach. B) A biopsy needle is used to puncture through the pouch and into the adjacent lumen of the remnant stomach. C) Contrast is injected to confirm intraluminal positioning of the biopsy needle. D) Carbon dioxide insufflation is used to distend the gastric remnant creating apposition between the anterior abdominal wall and the gastrostomy. E) Anterior and F) Lateral view of the gastric access to the remnant stomach utilizing the introducer method (see Chapter 9 for more detailed description of this method).

Roux-en-Y Gastric Bypass (RYGB) Gastric Pouch

Establishing enteral access into the gastric pouch may be required in post-RYGB patients who present with refractory marginal ulcer and/or gastric outlet obstruction at the gastrojejunal anastomosis. PEG tube placement into the gastric pouch may be challenging for a number of reasons. A standard restrictive gastric pouch measures 30cc, at least in the early postoperative period, allowing little room for placing a gastrostomy tube with bumper or

balloon. In addition, the gastric cardia sits anatomically above the costal margin, making it inaccessible to percutaneous access methods in most cases. However, attempts at endoscopically placing enteral access tubes are warranted in appropriate clinical settings with acceptable patient anatomy. In the setting of a chronic obstruction, for example, the gastric pouch may be substantially dilated and therefore be accessible below the costal margin. In addition, if outlet obstruction was the indication for enteral access, a gastrostomy tube with jejunal extension should be considered if possible, to provide gastric decompression through the gastric port and enteral nutrition through the jejunal extension.

A radiographically placed G-tube may be required in these cases due to inability to safely access the gastric pouch by endoscopy alone, due to its location above the costal margin. See Chapters 12 and 15 for additional details about radiographic assisted PEG tube placement.

Adjustable Gastric Band (AGB)

Indications for PEG following AGB are the same as for those in the non-bariatric patient (see Chapter 2). The presence of the band itself may be the sole or contributing factor to the patient's dysphagia. Deflating the band should be in the treatment algorithm for any AGB band with dysphagia or odynophagia.

The method of PEG placement in an AGB patient does not differ substantially from the methods described in Chapters 7 and 8. We find the Pull method technically easier to perform in the post-AGB patient as the dilating tip and/or the silicone retention dome of the gastrostomy tube itself can get hung up at the level of the band, resulting in resistance to forward tube advancement with the Push method. Complete deflation of the AGB facilitates both methods of PEG.

TECHNIQUES: DIRECT PERCUTANEOUS ENDOSCOPIC JEJUNOSTOMY (DPEJ) TUBE

Roux-en-Y-Gastric Bypass

Direct Percutaneous Endoscopic Jejunostomy (DPEJ) was originally described as an option for establishing enteral feeding in total and subtotal gastrectomy cancer patients to treat chronic malnutrition, dehydration, and failure to thrive [31-34]. DPEJ has since been utilized in post-RYGB patients who suffer from intractable nausea, gastric outlet obstruction, refractory ulcerations, malnutrition and dehydration. In patients with unaltered anatomy, deep jejunal access requires balloon-assisted endoscopy to traverse beyond the ligament of Treitz. In RYGB patients, however, deep jejunal access is simplified by the gastrojejunal anastomosis, which permits easy intubation of the jejunum. Despite rapid access to the anatomically more distal small bowel, determination of the post-surgical anatomy is important prior to proceeding with establishing enteral access in RYGB patients.

Special attention must be paid to whether the gastrojejunostomy was created in a retrogastric or antegastric fashion as well as whether the alimentary limb was placed in a retrocolic or antecolic position. This information can be obtained from the prior operative

note or by obtaining a CT with enteric contrast (or while a naso-jejunal tube is in place) to better delineate the anatomy. Patients who have had their RYGB created with an antegastric, antecolic configuration provide a better opportunity for successful DPEJ as the proximal jejunum is affixed in a more anterior position that will likely be more easily accessible for percutaneous puncture (Figure 3). Patients with a retrocolic RYGB construction will require more care taken to avoid injury to the colon as it passes over the alimentary limb. If there is concern for harm to overlying bowel, simultaneous colonoscopy and fluoroscopy with intraluminal contrast injection can be used to help identify the colon prior to passing a needle.

DPEJ placement is more challenging than standard PEG or percutaneous endoscopic gastrojejunal (PEGJ) placement due to the smaller target, difficult transillumination, and continuous peristaltic waves of the small bowel [35-6]. To improve successful endoscopic placement some advocate the use of glucagon or another antiperistaltic agent to decrease motility during key portions of the procedure [37]. Alternatively, gastrointestinal T-anchors can be used to rapidly affix the appropriate segment of bowel once the desired location has been selected. Although the native jejunum typically lies within the left upper quadrant, the surgically-altered anatomy means that the most anterior segment of bowel could lie anywhere within the abdominal cavity. Again, knowing the anatomy preoperatively is key to success in this operation, and liberal use of fluoroscopy is a useful adjunct. Owing to this variability, the entire abdominal wall should be sterilely prepared to avoid any delay once the site of maximum transillumination is identified.

Figure 3. Post RYGB patient in need of durable enteral access following an intra-cerebral hemorrhage. A) CT scan obtained with NJ tube in position demonstrates an antecolic, antegastric bypass and a safe window for DPEJ directly beneath the left rectus muscle (arrowhead) B) CT scan obtained after DPEJ demonstrates the tube to be in an anticipated position.

Figure 4 demonstrates the steps of DPEJ in a post-RYGB patient. After adequate preparation, the endoscope is then passed orally and advanced to the gastric pouch. A scout fluoroscopy film prior to introduction of the endoscopy can help identify the location of the colon (Figure 4A). After traversing the gastrojejunal anastomosis the endoscope is advanced 10-20cm into the jejunum. Transillumination and finger palpation are used to localize a segment of bowel against the anterior abdominal wall. Fluoroscopy can be used to confirm this location (Figure 4B). Once an appropriate segment is identified, standard steps for PEJ tube placement are employed beginning with a safe tract method (Figure 4C). Surrounding this safe tract, gastrointestinal T-anchors can be placed as desired (Figure 4D) [38]. The lumen is accessed with a core needle (Figure 4E), a wire is passed, and a snare is used to grasp and extract the wire into the lumen (Figure 4F). Because of the narrow caliber of the intestine, a Ponsky-pull technique is used to place a smaller, such as 20F, gastrostomy tube to minimize the risk of intestinal obstruction caused by the tube bumper (Figure 4G) [21]. If desired, a jejunal feeding extension can be passed distally into the small bowel and secured with endoclips (Figure 4H and I). This feeding extension has two roles, the first is to ensure that feeds do not reflux into the small gastric pouch and result in aspiration, the second is to reduce confusion about the presence of a 20 Fr tube in the left abdomen which may be incorrectly assumed to be a gastrostomy. The jejunal extension may therefore reduce the risk of inadvertent administration of bolus feeds to the small bowel. Contrast fluoroscopy can also be used to confirm correct placement of the tube at the completion of the DPEJ (Figure 4J) [39].

A modification to this technique has been described in an animal model utilizing intraluminal and extracorporeal magnetics to improve jejunal apposition to the abdominal wall prior to DPEJ placement [40]. The authors report a 100% success rate in establishing enteral access using this device; however such devices are not yet approved for human use.

Sleeve Gastrectomy

Sleeve gastrectomy has much less malabsorption compared to RYGB, as it only involves removing the distensible gastric fundus and does not alter intestinal continuity. DPEJ in post-VSG patients therefore follows the same steps of DPEJ in native anatomy. However, because of the small gastric body, BAE (with or without the use of endoscopic overtubes) or the use of a colonoscope *per os* are frequently not required [41]. DPEJ placement for VSG patients should only be considered in the setting of a well-healed, intact sleeve, as the large diameter of the working devices or the forces needed to advance the endoscope could lacerate or risk perforating a tenuous staple line [42].

To begin the procedure, again the entire abdominal wall is prepared to avoid delay once a suitable loop of bowel is identified. Endoscopy is performed and the endoscope is advanced until an appropriate loop of bowel, approximately 20cm beyond the ligament of Treitz is selected. The intraluminal location is approximated to the abdominal wall using a combination of transillumination and palpation. A hollow bore needle is used to puncture the jejunal loop under endoscopic visualization, and return of bubbles confirms placement. A wire is passed through the needle and an endoscopic snare is used to draw the wire retrograde. The remainder of the DPEJ tube placement is performed using standard PEJ technique. Because of the narrow caliber of the intestine, a 20F tube is again used to minimize the risk of

intestinal obstruction. Gastrointestinal T-anchors are always placed longitudinally to affix the bowel to the abdominal wall and prevent inadvertent tube dislodgement and free perforation. Chapter 10 covers the steps of DPEJ in greater detail.

Figure 4. Direct PEJ in an antecolic antegastric RYGB patient. A) Scout fluoroscopy film identifies air within the transverse colon (arrowheads) B) The endoscope is visualized within the alimentary limb and the location of maximal transillumination is marked with the blunt tip needle C) A safe tract method is used to confirm the correct location before D) Gastrointestinal T-Anchors are placed E) A guide sheath and needle are passed into the jejunum and F) A guidewire is grasped with a snare and withdrawn *per os* G) A 20 Fr gastrostomy is positioned (note that it is not obstructing the lumen) H) A jejunal extension is introduced via the 20 Fr tube I) The jejunal extension is advanced distally and clipped to the mucosa J) Completion contrast study demonstrates the 20 Fr DPEJ, jejunal extension, endoclips and contrast filling the distal alimentary limb.

CONCLUSION

Endoscopy plays a crucial role in the diagnosis and treatment of many post-bariatric surgical complications. Management can include closure of leaks, establishing feeding access, and creating enteral access to permit endoscopic therapy in the post-surgical anatomy. Anatomy can vary substantially and an accurate understanding and recognition of this variability is essential prior to performing such procedures. The method and type of access may be guided by which bariatric operation was performed and the exact indication for access. Despite an overall low complication rate, the number of weight loss surgical procedures performed annually mandates that endoscopists be well-versed in the options for establishing endoluminal enteral access to assist in management and treatment of the unique pathology that can arise in post-bariatric surgical patients.

Chapter 136

ALTERNATIVE USES OF PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Heidi J. Miller, MD and Jeffrey M. Marks*, MD

University Hospitals Case Medical Center, Cleveland, OH, US

INTRODUCTION

Since its introduction in 1980 in Cleveland, PEG technique has been performed and studied for a wide array of uses. The most common indications (as described elsewhere in this book) are impaired swallowing due to a number of causes, catabolic conditions requiring supplemental nutrition, and delivery of hydrating fluids or medications [1]. Other uses that have been described include decompression of benign and malignant gastrointestinal (GI) tract obstruction, refeeding of biliary and GI tract losses, colonic access, gastropexy, GI access for procedural intervention, esophagostomy, management of leaks and fistulas and natural orifice transluminal endoscopic surgery (NOTES) [1, 2]. This chapter provides an overview of the alternative uses of PEG technique beyond affording a route for enteral nutrition.

DECOMPRESSION

The most commonly recognized “alternative” use of the PEG described in the literature and among gastroenterological societies is the “venting” gastrostomy for decompression of the GI tract. This is primarily utilized in the setting of bowel obstruction, both benign and malignant. Other indications for decompressive PEG that have been studied include gastroparesis and prolonged ileus.

The use of PEG tubes for decompression of patients with malignant bowel obstructions has been found to be both safe (with a minor complication profile) and successful at eliminating the need of nasal tubes in most patients [3]. Decompression via venting

* Corresponding Author’s Email: jeffrey.marks@uhhospitals.org.

gastrostomy is utilized similarly to stenting and surgical interventions in the presence of malignant bowel obstruction to treat intractable nausea and vomiting. The venting PEG has a 92% success rate and serves to permit removal of nasal tubes, treat symptoms and increase quality of life by allowing resumption of oral fluids and soft food intake for comfort and social reasons. The complications are few and mild including pain, leakage, skin excoriation and tube blockage. If a PEG is not possible or adequate, percutaneous endoscopic jejunostomy (PEJ) or percutaneous transesophageal gastrostomy (PTEG) have also been found to be successful [4]. See Chapters 10 and 12, respectively, for further discussion on PEJ and PTEG.

Venting gastrostomy tubes should be used in combination with well managed medical and pharmacologic interventions [5]. Kawata et al. placed PEG tubes in 76 patients with malignant obstructions over the course of 10 years using either the pull or modified introducer method, and placed gastrojejunostomy tubes where indicated [3]. They showed a 93% success rate for placement, 96% reduction in the need for nasal tubes and a 21% complication rate (mostly leakage or infection around the gastrostomy). The median survival was 63 days (range 8-444 days) with no procedure related mortality. Outcomes in malignant bowel obstruction seem to be related more to the patient's functional status and disease-free time than intervention type, and the average median survival following decompressive PEG is around 80 days [5].

Decompressive PEG has also been found to be safe and effective in the management of obstructive symptoms in benign disease in patients who cannot be easily managed with surgery, ultimately allowing removal of the nasogastric tube and discharge from the hospital [6]. Such conditions include non-malignant obstruction, motility disorders, need for diversion of gastric contents, and prolonged ileus. The literature is limited to a few small case series and retrospective reviews of subgroup outcomes within larger series of obstructed patients, evaluating nonmalignant indications for decompression. There is a high success rate of placement of PEGs with a low complication profile and they can play three ultimate roles: bridge to surgical therapy, intermediate therapy allowing for resolution of obstructive/paralytic pathology, and permanent venting gastrostomy in a small number of patients [7-9].

Daigle et al. report a retrospective review of 72 patients over 5 years who underwent decompressive PEG for nonmalignant indications including postoperative ileus, dysmotility, chronic or subacute small bowel obstruction (SBO), benign gastric outlet obstruction, superior mesenteric artery syndrome, and complicated SBO with contraindications for immediate surgical intervention. Only one procedural complication of PEG-associated bleeding was reported and there were no procedure related mortalities. Fifty-two patients were followed long term and PEG was kept in place for a median of 69.5 days (range 17-316 days). Sixty-three patients were discharged on total parenteral nutrition (TPN). The 36 patients that were followed long-term received TPN for a median of 51 days but ultimately achieved resolution of their obstructive problems and were able to resume enteral nutrition. Three patients became chronically TPN-dependent and their PEG tubes remained in place [7].

In a small series of PEG use for prolonged ileus, Takayama showed that patients tolerated PEG better than nasogastric tubes, and PEG decompression provided better outcomes. PEG tubes allowed 4 of 5 patients to improve without surgical intervention and one patient to improve functional and nutritional status preoperatively. All five of these patients eventually had their tubes clamped, tolerated oral feeds and tubes removed in succession [9].

Figure 1. Endoscopic rendezvous technique for intercostal PEG placement. A) CT guided placement of pigtail tube through the intercostal space due to carcinomatosis limiting safe PEG placement for decompression of malignant bowel obstruction. B) Endoscopic view of intercostal pigtail tube in the lumen of the stomach. C) Endoscopic view of decompressive PEG following exchange of the intercostal pigtail catheter.

The European Society for Pediatric Gastroenterology Hepatology and Nutrition recognizes gastric stasis as an indication for PEG placement in pediatric patients. The use of PEG in gastroparesis in pediatric patients can be for venting via gastrostomy alone but also allows for transpyloric feeding with the use of a jejunal feeding extension tube (PEG-J) [10]. The clinical guidelines for management of gastroparesis by the American College of Gastroenterology also discuss the use of a gastrostomy. Gastrostomy for venting and jejunostomy for enteral feeding in the management of gastroparesis is a conditional recommendation due to the lack of evidence [11]. However, the PEG-J provides benefits over a simple jejunostomy and gastrostomy by allowing venting of the stomach to decrease or prevent emesis, as well as providing post-pyloric feeds through distal J-tube ports. This also comes with potential complications such as J-tube migration into the stomach, obstruction at the pylorus and potential interference with gastric stimulator placement, but reduces the potential complications compared to two separate access sites [11].

Finally, PEG and direct percutaneous tube enterostomies have been described for decompression of afferent loop obstruction following surgical gastrojejunostomy [12].

Technical Pearls

Safe percutaneous access to the stomach can be difficult in the patient with a hostile abdomen, either due to malignancy or severe adhesive disease secondary to multiple surgeries. Radiologic guidance for pigtail catheter placement into the stomach can be used in these cases as well as in patients where safe tract or transillumination below the costal margin cannot be achieved. An endoscopic rendezvous technique can be used for intercostal placement of PEG for palliative uses. This includes radiologic guided insertion of intercostal pigtail tube and the PEG is then placed endoscopically through the created track (Figure 1). PEG technique may also be utilized to aid in difficult open gastrostomy cases, such as a frozen abdomen, to safely identify and place a decompressive tube.

GASTROPEXY

Paraesophageal hernia (PEH) can often be asymptomatic in elderly patients but large PEH hold a 30-45% risk of incarceration, volvulus or strangulation. These complications can have up to a 50% risk of mortality which leads surgeons to be more aggressive in definitive repair at early stages. Laparoscopic repair with recreation of normal anatomy, intraabdominal esophagus, and closure of the crural defect is the standard of care. However, as the population ages and incidence of large PEH increases, so do the comorbid conditions with which patients present. Open repair of PEH has been shown to have up to 27% morbidity rates and 1-2% mortality and elective laparoscopic repair has been reported to have up to 28% morbidity with a 16% major complication rate. Endoscopy is the most logical approach for a less invasive but effective palliative and preventive procedure [13]. The second most common alternative use of the PEG is gastropexy in the setting of PEH or gastric volvulus.

Endoscopic reduction of large PEH was described in the literature in the 1990s, starting with a small series where this was used as a bridge for optimization for definitive surgery. This then led to the use of the dual PEG technique for gastropexy (Figure 2). There have been single cases and case series that describe both laparoscopic and endoscopic gastropexy for the treatment of large PEH, but these report a higher recurrence rate compared to the use of PEG [13]. Kercher et al. describe a series of 11 high risk elderly patients with symptomatic large PEH that were treated with either endoscopic reduction and dual PEG placement or laparoscopic-assisted endoscopic reduction and dual PEG placement [13]. Pull-PEGs were placed in the mid body and antrum with at least a 12 inch interval between the tubes to allow for definitive gastropexy. Tubes were left in place for 2 months. Lap-assisted cases also had laparoscopic gastropexy sutures placed to reinforce the PEG gastropexy. Of these 11 patients, three had mild reflux symptoms and one had evidence of an asymptomatic recurrent sliding hiatal hernia at 2 months [13]. More recently, multiple case reports for the treatment of gastric volvulus, obstruction or incarcerated PEH have been published. These techniques can include laparoscopic repair and reduction with PEG gastropexy, endoscopic reduction with PEG gastropexy or endoscopic reduction with percutaneous gastropexy devices (Figure 3) [14-18]. See Chapter 9 for a more indepth discussion of methods of endoscopic and laparoscopic gastropexy.

There are reports of recurrent volvulus and herniation with the use of single PEG gastropexy and suture gastropexy alone, as both of these create another potential axis for rotation [13, 19]. Therefore, a dual PEG or multiple gastropexy site technique is recommended.

Figure 2. Endoscopic view of dual PEG technique for gastropexy.

Figure 3. Abdominal view following endoscopic reduction and gastropexy with PEG, gastrointestinal T-anchors (*) and a permanent gastropexy stitch (arrowhead) placed with a transfascial suture passer.

Technical Pearls

It is prudent to perform these procedures in the operating suite with the option to provide airway protection, sedation or general anesthesia as needed and for laparoscopic assistance in some cases. Fluoroscopy is also helpful in some cases for external visualization of anatomy

and scope placement (Figure 4). Endoscopic reduction of gastric herniation or volvulus may be accomplished with slow advancement and insufflation of the endoscope, being careful to maintain a view of the gastric lumen. A pediatric colonoscope may be used as its added length may be necessary to fully traverse the gastric volvulus and resultant gastric distension. Aggressive use of suction is beneficial to decompress the incarcerated stomach prior to endoscopic reduction below the diaphragm.

Figure 4. Endoscopic and fluoroscopic reduction, PEG and gastropexy of incarcerated hiatal hernia. A) Endoscopic view of the obstructed cardia. B) Fluoroscopic view of the air filled cardia above the diaphragm. C) Endoscopic and D) fluoroscopic view of partly reduced stomach with the gastroscope in retroflex. E) Fluoroscopic view of the completely reduced stomach with the gastroscope holding the stomach in an intraabdominal position while F) gastrointestinal T-anchors are placed. G) PEG bumper and surrounding T-anchors (arrowheads) on endoscopy and H) fluoroscopy. I) View of the abdomen shows PEG and T-anchors.

In the dual gastroscope technique, one gastroscope may be left in place along the greater curvature, weighing the stomach down in a reduced anatomical position while another is placed alongside for PEG placement. Alternatively, a first PEG may be placed in the antrum to hold the stomach in position and a second in the body of the stomach for dual PEG gastropexy. A standard colonoscope passed per rectum under fluoroscopy may be used to move the transverse colon into the pelvis and out of the path of the PEG gastropexy [13, 14, 16].

COLONIC INTERVENTION

The percutaneous endoscopic colostomy (PEC), which can be placed with the same techniques described for PEG has seen some fluctuations in indication and breadth of use since the 1980s when PEG was first becoming popular. The PEC is generally used as an alternative to surgical intervention in patients with many comorbidities or contraindications for surgery. Indications for PEC described in the literature are acute colonic pseudo-obstruction, recurrent sigmoid volvulus, constipation, and neurogenic bowel. Complications that have accompanied these uses include, self-limited bleeding, stercoral peritonitis, sepsis, and seizures. Most published cases have resulted in the resolution of the underlying problem and eventual removal of the PEC [20].

Multiple percutaneous endoscopic approaches to recurrent or chronic sigmoid volvulus have been described, including a singular PEC, multiple gastrointestinal T-fasteners and percutaneous endoscopic sigmoidopexy with buried sutures. Each comes with advantages such as potential use of decompressive tube, nonpermanent sutures, and multipoint permanent fixation respectively [21]. Bruzzi et al. described the management of acute sigmoid volvulus in 65 patients over 10 years. As first line treatment 95% underwent nonsurgical reduction, and two-thirds of patients had recurrence. Thirty-three patients underwent prophylactic surgical resection and six patients underwent percutaneous endoscopic colostomy. These patients were elderly (84-99 years-old) with median ASA 4 and all were neuropsychiatric inpatients. There was a 67% complication rate, mostly local site infections, pain and bleeding and 50% mortality rate from causes unrelated to volvulus. There was only one recurrence amongst the PEC treated patients after the tube was removed. The procedure does not require general anesthesia and is quicker and easier than a colon resection. Post procedure, patients should be placed on antibiotics and observed after the procedure [22].

Indications have been expanded to PEC for fecal incontinence and chronic constipation using a PEG kit and technique in the cecum. One reported case in an adult had four months of follow up with resolution of fecal incontinence using the PEC with daily saline irrigation [23]. PEC button placement for antegrade enemas in chronic constipation and incontinence in children has been described. Twenty-six cecostomy and three sigmoidostomy trap door buttons were placed by Becmeur et al. without complication and this reversible procedure improved quality of life for patients and caregivers [24].

National Institutes for Health and Clinical Excellence published guidelines for PEC in 2006 and found evidence that supported PEC as an adequate procedure in elderly or frail patients with recurrent sigmoid volvulus and colonic motility problems. However, for the use of PEC in children with chronic constipation further evidence is needed. Good patient

selection and a multidisciplinary team approach (include a pediatric gastroenterologist and colorectal surgeon) should be employed. The guidelines also emphasize that true informed consent should be discussed with the patient and information about the risk of peritonitis should be made clear [25].

Advantages of PEC are the ability to safely be performed without general anesthesia and they can be removed when the underlying pathology has resolved. Considerations are post procedure antibiotics and observation, avoiding traction, and rapid replacement to skin level button type tubes. The complication profile of PEC has been describe above, but care should be taken and patients followed as multiple cases of peritonitis have been described as far as 6-8 weeks out from the procedure [20, 26].

Figure 5. PEG assisted ERCP following Roux-en-Y gastric bypass. A) CT scan demonstrating percutaneously placed PEG in the remnant stomach. B) Fluoroscopic image of UGI via PEG tube. C) Fluoroscopic image of transgastric ERCP being performed via the gastrostomy tract in the remnant stomach.

GASTROINTESTINAL TRACT ACCESS FOR PROCEDURES

With increasingly successful surgical treatments of complex disease and improved survival, more patients present an unusual challenge of accessing the GI tract for otherwise commonplace procedures. PEGs may be useful in such situations especially in cases of esophageal stricture or obstruction or due to altered anatomy such as in post gastric bypass patients. With the obesity epidemic reaching 35% of the US population, the rates of weight-loss surgery continue to increase and Roux-en-Y Gastric Bypass (RYGB) is a common

procedure. As 50% of RYGB patients develop gallstone disease and many require pancreaticobiliary intervention, the challenge of endoscopic retrograde cholangiopancreatography (ERCP) in gastric bypass patients is real.

Transgastric ERCP can be done surgically or percutaneously with laparoscopic and/or radiographic assist, both of which require the collaboration of two teams and are fraught with complications, high costs and significant failure rates. Thus laparoscopic-assisted ERCP with the use of PEGs have become increasingly more common (Figure 5) [27]. This is commonly done in multiple stages and often requires postponement of the ERCP for 4 weeks to allow the PEG tract to mature. However, Law et al. have shown the efficacy and safety of a single session transgastric ERCP. The gastric remnant was reached using balloon enteroscopy and a retrograde PEG was created and maintained using a self-expanding metal stent (SEMS) (Figure 6), through which the duodenoscope was advanced. Once the ERCP was completed a PEG tube was placed to maintain the stoma if needed for further access [28]. Endoscopic ultrasound has also been employed for creation of a PEG into the remnant stomach for ERCP access [27]. Fluoroscopy and SEMS are used in both cases to increase the success and safety of the procedure.

Figure 6. Percutaneous self-expanding metal stent and gastrointestinal T-anchors within the gastric remnant in a patient following Roux-en-Y gastric bypass. The gastrostomy tract created by the stent was subsequently used to perform a transgastric ERCP.

PEGs are used to access the GI tract for endoscopy for other purposes as well and an ultrathin endoscope may be used through the PEG stoma site for access. This is especially useful in patients with esophageal stricture or obstruction and can be used for retrograde identification of the esophageal lumen for dilation or transillumination of short segment strictures. Complete obstruction of the esophagus may be treated with retrograde submucosal tunneling via a previously placed PEG [29]. Stent placement is another possible use of PEGs either in patients with esophageal stricture or to improve angulation of the stiff stent deployment devices. Some of these uses include: drainage of a malignant biliary stricture with a transgastric biliary stent, placement of direct percutaneous jejunostomy feeding tube via a

PEG, endoscopic treatment of marginal ulcer following trauma requiring esophageal discontinuity, and intraluminal surgery for multiply recurrent hiatal hernia with gastric herniation [29-32].

Although PEG tubes with J extensions have been used for palliation of malignant gastric outlet obstruction, gastroduodenal stents have been found to have better patency and survival [33]. These stents may be placed either through in-situ PEGs or via a PEG-like pathway using a sheath catheter for insertion which may ease the angulation of the deployment device as well as allow for PEG tube placement for ease of access as further stenting is required [34].

MANAGEMENT OF LEAKS AND FISTULAE

PEG tubes and stomas have been used for the management of gastrointestinal leaks and fistulas in many ways. PEG as a drainage tube to decompress the stomach and divert gastric contents has been shown to help with healing of GI fistulous disease and can be used to bridge patients to surgery over the course of a few months and allow for improved nutritional status [8]. PEG tubes with jejunal extension tubes have been used in this method for the management of colo-duodenal fistula in the setting of Crohn's disease. A double lumen gastrojejunostomy tube placed past the fistula site along with ileostomy for treatment of the colonic stricture was used to bridge to surgery after two months where the gastrocolonic fistula was found to be nearly healed [35].

Figure 7. Decompressive esophagostomy tube replacement. A) Endoscopic view of the distal esophagus demonstrates free intraperitoneal communication and a purse string suture that previously secured the surgically placed tube. B) Rendezvous with a percutaneous guidewire within the old tube tract establishes communication from skin level to distal esophagus. C) PEG bumper in position in the distal esophagus D) Fluoroscopic image demonstrates contrast in the distal esophagus decompressing via the PEG. The small amount of leak around the tube is adequately controlled with the percutaneous drain.

Gastric perforation after chemotherapy for diffuse large B-cell lymphoma has been treated in a similar manner [36]. Negative pressure sponge therapy has been shown to be effective in treating esophageal anastomotic breakdowns or perforations and these therapies have had their indications expanded to include other areas of the GI tract [37]. Glatz et al. used negative pressure to heal an iatrogenic duodenal perforation and employed the PEG tube to hold the sponge and tubing in place to prevent migration and to allow ease of changing the sponge. They showed closure of the perforation at 20 days and were able to remove the PEG one week later [38].

PEG tubes can be used to help manage fistulas, leaks or perforations either through decompression and diversion of GI contents, bypassing the problem for enteral feeding, or aiding in the placement or use of other devices. Juza et al. described a modified PEG rescue technique to replace a dislodged decompression tube in a patient with a blind ending abdominal esophagus following an emergency total gastrectomy without reconstruction (See Chapter 20 for more information on PEG Rescue) [39]. The patient presented with an intra-abdominal leak from the distal esophagus. Once wire access was achieved between the old tube tract and the distal esophagus, a pull-type PEG method was used to position the bumper in the distal esophagus under fluoroscopic guidance to decompress the esophagus and eliminate leak (Figure 7).

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY (NOTES)

As NOTES is being explored to further reduce the invasiveness of surgical procedures and allow for intervention on even the sickest of patients, it has emerged as a potentially valuable tool for urgent intervention of intra-abdominal emergencies [40]. PEG is being studied in animal models as an access point for expansion of possible NOTES procedures including repair of ventral hernia with mesh [41-43].

CONCLUSION

As the population ages and minimally invasive surgical techniques evolve, the indications and uses for percutaneous endoscopic gastrostomy will continue to expand. Endoscopists must be aware of the expanding indications for PEG to employ them for the benefit and safety of patients.

EDITOR'S COMMENT

As Dr. Marks clearly knows from his training with Dr. Ponsky, the utility of a percutaneously placed gastrostomy and PEG technique extends well beyond enteral feeding access. The ability to place a PEG under sedation to alleviate symptoms of a bowel obstruction, reduce an incarcerated hiatal hernia or as part of the management strategy for a fistula means that patients with highly morbid conditions can be managed in as minimally

invasive a fashion as possible. The coming years are likely to see even more techniques based on PEG technique. (EMP)

Chapter 137

POSTOPERATIVE MANAGEMENT

***Fazia A. Mir, MD, Douglas L. Nguyen, MD
and Matthew L. Bechtold*, MD***

University of Missouri, Columbia, MO, US

INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) is the most commonly performed enteral feeding procedure for long-term enteral nutrition in patients with dysphagia due to a variety of causes (especially neurologic and neoplastic). PEG tubes are placed if enteral feeding is required beyond four weeks of hospitalization with life expectancy greater than two months [1]. PEG tubes can also be placed for gastric decompression in patients with gastroparesis or malignant obstruction [2].

Although PEG placement is done by a wide array of practitioners (gastroenterologists, general surgeons, neurosurgeons, medical and surgical intensivists, otolaryngologists, interventional pulmonologists and thoracic surgeons), once the PEG is placed, post-gastrostomy care is pivotal and should be standardized. PEG care is focused on feeding (or decompression), maintaining a functional gastrostomy, and early recognition and treatment of potential complications. In this chapter, we focus on post-operative management of PEG with emphasis on the clinicians' perspective with suggestions on when to initiate feeding and how to handle potential major and minor complications associated with PEGs.

ENTERAL FEEDING AFTER PEG PLACEMENT

Delays in feeding after PEG placement can result in prolonged hospital stays, malnutrition, and increased health care expenditures. Based on surgical dogma regarding intra-abdominal surgery, it has been common practice to wait 24-48 hours before initiation of tube feeds after PEG placement. This practice was based primarily on clinical experience with

* Corresponding Author's Email: bechtoldm@health.missouri.edu.

the reasoning being a possible increase in gastric residual volume after surgical manipulation of the gut [3].

A meta-analysis by Bechtold et al. demonstrated no difference in complication rate or short-term mortality in patients who received early PEG feeding (defined as ≤ 4 hours post procedure) compared with delayed or next day feeding (Table 1) [3]. Furthermore, a large retrospective 5-year study in an institution that practiced early feeding (within 4 hours post procedure) demonstrated no differences in complications between early and delayed feeding [4]. Data is changing the dogmatic practice of delayed feeding and more centers are initiating tube feeds 3-6 hours after PEG placement without any noted increase in adverse events or complications. Emerging data demonstrates the safety and feasibility of initiating tube feeds as early as 3-4 hours after PEG placement [5-6]. Anecdotally, some practitioners begin or resume tube feedings immediately after PEG placement in the absence of another clinical contraindication. It should be noted, however, that there is no large study to support this practice.

It is recommended that tube feeds should be started in conjunction with dietician and the use of an appropriate enteral feeding supplement. During feeding, the patient must be positioned at a 45 degrees head-up angle while being fed to prevent reflux and aspiration [7]. After feeding through the tube, the tube should be flushed with 50 mL of water and the tube rotated clockwise to prevent injury and pressure ulcer formation at the abdominal wall. Rotating the tube in conjunction with routine feedings is not mandatory, but since the tube is being accessed at this time it is a convenient way to coordinate two nursing care events.

Prevention of aspiration is important as aspiration pneumonia is fatal in 17-62% of cases [8]. Risk factors for aspiration pneumonia include a previous history of aspiration, vomiting, gastro-esophageal reflux, anatomic abnormalities (hiatal hernia, gastric outlet obstruction), and prolonged supine position [9]. Many of these conditions can be identified on the diagnostic endoscopy performed during PEG (see Chapter 6), highlighting the importance of the endoscopist communicating these findings to the patients primary management team.

A prospective study done recently noted that re-aspiration within 6 months of PEG placement was lower when compared to oral feeding and nasogastric tube feeding. However, PEG placement did predispose to aspiration risk and was not 100% protective against it [10].

Table 1. Meta-analysis outcomes of early (≤ 4 hours) versus delayed/next day feeding after PEG placement [3]

OUTCOME	ODDS RATIO	95% CONFIDENCE INTERVAL	p-VALUE
All Complications	0.86	0.47-1.58	0.63
Mortality ≤ 72 hours	0.56	0.18-1.74	0.31

Aspiration risk can be reduced by proper posture when administering feeds, control of esophageal reflux, and avoidance of over-feeding the patient [7, 11].

Early feeding (as defined as feeding ≤ 3 hours after PEG placement) also did not have any association with increased gastric residual volumes during the first 24 hours [12]. A great deal of debate has occurred over the use of gastric residuals as a guide for aspiration risk. In critically ill patients, gastric residual volumes are also no longer a guide for enteral nutrition as the risk of ventilator-associated pneumonia was not associated with an increase if gastric residual volumes were not checked [13]. In the future, constant checking of gastric residual volumes may be significantly diminished.

ENTERAL DECOMPRESSION AFTER PEG PLACEMENT

If the tube has been placed for decompression of the GI tract, then the tube can be left open to gravity drainage by connecting it to a biliary or urinary collection bag. If the volume of output is anticipated to be high, some practitioners leave a nasogastric tube in for decompression for the first 48 hours to reduce the risk of early intra-peritoneal leak from high gastric volumes. If the volume of output is anticipated to be low, the tube can be clamped and opened intermittently (either on a scheduled basis or when symptoms arise) by either the caregiver or the patient. The addition of tubing and a collecting bag to the PEG can add traction to the device and present an additional risk for early tube dislodgement. Care should be taken when the patient is transitioning (e.g., into or out of bed, etc.).

MECHANICAL MANAGEMENT OF THE GASTROSTOMY

Preventing Premature Removal of PEG

In an agitated or combative patient, or occasionally with routine patient care or activities of daily living, PEGs can become accidentally dislodged within the first 7 days of placement. Within this time frame, the PEG tract has not had time to mature and lack of adherence of the gastric wall to the abdominal wall can result in the contamination of the peritoneal cavity with gastric contents, resulting in peritonitis. If peritonitis occurs, treatment should be initiated with antibiotics and surgical consult should be initiated. See Chapters 18 and 20 for more information about the management of early PEG dislodgement.

To prevent this complication, post-PEG placement abdominal binders may be used for patients who are at high risk for pulling out the tube inadvertently [14]. Abdominal binders have been deemed safe in most cases; however, they do pose a risk for gastric and/or skin breakdown by mechanical pressure caused by torsion [15, 16]. To prevent this complication, the binder should be oversized to the patient and/or placed loosely around the abdomen (Figure 1). The primary function of the binder is to provide a mechanical barrier to the tube to prevent a patient with altered sensorium from easily grasping the tube.

Figure 1. Abdominal binder placed loosely to protect a newly-placed PEG.

Figure 2. PEG secured to the skin with a tape 'mesentery.'

Figure 3. Gastrointestinal T-anchors positioned in around a PEG tube in a patient at high risk for early tube dislodgement.

Other potential anchoring devices have been used to secure the PEG, most commonly tape (Figure 2). Some practitioners elect to suture the external PEG bumper to the skin while others avoid this practice due to concerns of skin ulceration/necrosis; there is limited data to support either of these practices. Gastrointestinal T-anchors, inserted through the abdominal wall into the stomach around the PEG (Figure 3), do not prevent early tube removal. They do, however, prevent an immature gastrostomy from falling away from the abdominal wall thereby minimizing the risk of peritoneal leak as a result of early tube dislodgement (Figure 4). Also, a safety break device has been developed by Rosenberger and colleagues to prevent accidental dislodgement of PEG tubes. In a trial, this device was noted to reduce accidental dislodgement by 51% [17]. If repeated dislodgement occurs, a low-profile PEG tube or permanent surgical gastrostomy (Janeway gastrostomy) should be considered (Figure 5).

Figure 4. CT scan of a patient following early PEG dislodgement. A) PEG bumper is located in a subcutaneous position with surrounding soft tissue stranding and air (arrow). B) Gastrointestinal T-anchors (arrowheads) prevented the gastrostomy from falling away from the abdominal wall preventing free intraperitoneal leak.

Figure 5. Janeway gastrostomy. A) Laparoscopic stapler creating a tubularized portion of stomach that is delivered to the skin surface and surgically matured. B) Endoscopic view of the anti-reflux valve and non-ballooned catheter placed via the gastrostomy.

Managing PEG Bumper Tension

Excessive force on the PEG bumpers can result in both gastric and abdominal wall erosions from tension induced ischemia. In the best case scenario, such ulceration is asymptomatic. In the worst case, significant bleeding (from erosion in to gastric or abdominal wall blood supply) or infection (including necrotizing soft tissue infections) can result (Figure 6). Such major complication may be prevented by multiple ways.

First, the skin incision made for the gastrostomy should be approximately 1 cm (Figure 7). If the incision is less than 1 cm, added pressure is applied on the tissue around the inserted PEG which may lead to decrease blood flow to the area and subsequent tissue necrosis. Second, the external bolster should be fastened no less than 2 cm (Figure 8).

Figure 6. Pressure induced full thickness abdominal wall erosion and superimposed infection as a result of excessive gastrostomy tension. This defect measures 3 x 3 cm.

Figure 7. Skin incision for PEG is slightly oversized for the diameter of the tube to prevent undo pressure on the skin. For a 20 Fr tube, 8 mm is appropriate, for 24 Fr, 1 cm is appropriate.

In many institutions, PEGs are tightly fastened for the first 24 hours after placement to ensure apposition of stomach and the abdominal wall. On the next day, the external bolster is loosened to the standard distance for the patient. Although a popular practice, it subjects the patient to potential complications without benefit. Given that the PEG tract takes weeks to fully mature, tightening the external bolster in the first 24 hours does little to ensure a secure PEG tract.

Figure 8. External PEG bumper sits above the level of the skin when tensioned correctly.

Figure 9. Correctly dressed PEG site has gauze over the top of the external bumper. Incorrectly positioning the gauze under the bumper adds tension to the internal retention dome placing the patient at risk for buried bumper syndrome.

Therefore, we recommend setting the external bolster at a preferred long-term distance at time of procedure, approximately 3 cm in most patients (depending on body habitus). In a respective study over 5 years where this management plan was employed, no major complications were identified (Table 2) [4]. In addition, many caregivers like to place gauze between the skin and external bolster. This also may be problematic as the distance between the external bolster and internal bolster is a fixed distance. By placing gauze in between the two bolsters, added pressure is applied to the tissue which may lead to erosion and/or buried bumper syndrome (BBS) (Figure 9).

BBS is a long-term complication of PEG placement and occurs at a rate of 1.5-2.0% [18]. In children with PEGJ tubes (PEG with jejunal extensions) the risk of developing BBS is increased, approaching 32% [18]. It can happen anywhere from months to up to years after PEG placement. BBS occurs when the internal bumper of the PEG tube erodes through the

gastric wall and into the abdominal wall. The gastric mucosa eventually covers the gastrostomy tube bumper.

Table 2. Post-procedure complications over a 5-year period where PEG (n = 444) was placed at ~3 cm mark [4]

Complication	Patients n (%)
Leakage	4 (0.9%)
Infection	5 (1.1%)
Bleeding	1 (0.2%)
Vomiting	15 (3.4%)
Stomatitis	4 (0.9%)
Mortality $\leq$ 72 hours	11 (2.5%)

Several risk factors have been implicated in the development of BBS and include increase tension on the tube with suboptimal PEG tube care [19]. Patients present with inability of tube feeds to normally pass thru the tube and inability to rotate the PEG tube [20]. Diagnosis can be confirmed endoscopically by failure to visualize the PEG tube bumper internally [21]. BBS can lead to further severe clinical complications such as wound infection, peritonitis, and necrotizing fasciitis [22]. Definitive treatment for BBS includes removal of the PEG tube by external traction, endoscopically, or surgically [23].

To prevent BBS, the external bumper should be loose and the PEG should rotate freely; however, the external bumper cannot be too loose as it can lead to PEG site leakage and peritonitis [24]. Avoidance of gauze between the external bolster and skin, having the external bolster slightly loose (~3-4 cm mark), and proper skin care are essential in preventing this complication.

Prevention of Tube Clogging

Feeding tubes get clogged with feeds or medications at a rate of 23-35% [25]. Feeding tubes need to be flushed with 30-60 mL of water after every tube feed and medication administration. Despite taking good care of the PEG, clogging can still occur at a rate of 15% [26]. If the PEG becomes clogged, common practice is to use pancreatic enzymes and carbonated beverages to unclog the tube with variable efficacy [17, 27]. A study in 1989 compared nine substances (pancreatic enzymes, pork pancreatin, bromelain, papain, cranberry juice, chymotrypsin, Coca-Cola, and distilled water) for effective unclogging of the PEG tube. It found that papain (commonly found in meat tenderizers) and chymotrypsin were most effective at de-clogging PEGs [28]. Commercially available medical devices such as PEG cleaning brush and 'Clog Zapper' are available but no trials are available to compare efficacy with other agents [29]. Furthermore, some commonly used substances, may results in damage

to the PEG itself. Novel devices, such as flexible motor-operated brushes, offer promise as a more effective method of tube clearance (Figure 10).

Managing PEG Site Leakage

PEG tube site leakage is reported in 1-2% of patients [30]. Factors that lead to PEG tube site leakage include bacterial or fungal infection of the stomal site, development of granulation tissue, use of excessive chemical cauterization with hydrogen peroxide or silver nitrate, inadequate acid suppression, and buried bumper syndrome [31].

Excessive leakage around a PEG may also happen with intolerance to tube feeds. If this is the case, cessation of tube feeds and placement of the PEG tube to gravity drainage may be helpful [32]. Patients should be started on a proton pump inhibitor to decrease acid production. Zinc oxide paste or nystatin powder can be used for local healing of PEG site. The cause of PEG site leakage should be sought and treated rather than changing the PEG tube to a larger size. Contrary to popular belief and practice, placement of a larger tube in the leaking PEG site, increasing the tension on the PEG bumpers, or overinflating a gastrostomy balloon will not help leakage and likely worsen the problem by creating a larger hole. Minimizing both tube movement and tension at the external bumper will help solve this problem. Conversion to a low profile button can sometimes meet fulfill both of these needs and allow for resolution of excessive leakage.

Figure 10. Electromechanical motor-operated device that can be utilized to unclog PEG tubes (TubeClear® System, Actuated Medical, Bellefonte, PA). The system is comprised of a re-usable control box and a single use 'Clearing Stem.' One end of the Clearing Stem is attached to the control box and the other end is inserted into the feeding tube. The mechanical motion of the control box actuates the Clearing Stem Wire Brush Tip as it is advanced through the tube to actively work on and remove the clog.

PEG Dysfunction and Replacement

PEGs may be removed once the condition requiring placement has resolved. This can be accomplished at 2-3 weeks after placement, with most clinicians preferring to wait 4-6 weeks. The delay in removal permits the tract to mature so that when it is removed there is not spillage of gastric contents into the peritoneal cavity. Once a PEG is removed, the gastrocutaneous fistula usually closes within 24-72 hours [2]. If the fistula does not close and leakage is a problem, the fistula may be treated with chemical cautery, managed endoscopically with special over-the-scope clips or endoscopic suturing, or surgically (See Chapters 19 and 20) [33].

Chronic conditions requiring PEG will need care and replacement every 6-12 months (See Chapter 19). PEG tubes can be changed at the bedside or in clinic by the percutaneous method which involves a strong and sustained pull until the internal bumper goes thru the stoma. For a balloon PEG, deflation of the balloon and gentle traction will remove the tube. A retrospective study compared the complication rate of PEG removal via traction method versus endoscopy removal and reported that the percutaneous method is safer to employ when removing the tube [34]. The tube can be replaced with a balloon gastrostomy or with a non-balloon PEG tube utilizing a rigid introducer to elongate the replacement PEG (Figure 11).

Figure 11. A) Replacement PEG tube with introducer. B) Internal PEG bumper has a dimple (arrowheads) into which the introducer is placed. C and D) Traction on the PEG against the introducer elongates and folds the bumper, allowing it to be pushed through the mature gastrostomy tract and into the stomach.

Anticoagulant/Antiplatelet Management

Reports of bleeding after placement of PEGs are rare but range from approximately 0-2.8% [35-37]. Bleeding can occur as a result of injury to the gastric or other mesenteric vessels, from the rectus sheath, from PEG tube site tumor metastasis, or from the retroperitoneum [38-41]. In regards to bleeding, the main concern of clinicians is the use peri-procedural anticoagulant or antiplatelet medications.

The American Society of Gastrointestinal Endoscopy (ASGE) 2015 consensus statement recommends that aspirin and clopidogrel/ticlopidine be held peri-procedurally for 5 days in an effort to prevent post-procedure bleeding but non-steroidal anti-inflammatory agents can be continued if there is no pre-existing coagulation disorder [42]. Large retrospective cohort studies have shown that the use of aspirin or clopidogrel did not appear to be associated with procedure-related bleeding in after placement of the PEG [36, 37, 43-45]. An observational study by Singh et al. did not find an increased risk of bleeding with the use of low molecular weight heparin (LMWH) [44]. Coumadin will need to be held, and the risks and benefits of doing this must be assessed (see Chapter 4).

If patient needs to be on therapeutic anticoagulation immediately, they it may be started [44, 46]. ASGE guidelines recommend that warfarin should be held 3-5 days prior to PEG tube placement and if the patient is high risk for thromboembolism, then LMWH or unfractionated heparin (UFH) may be instituted. LMWH should be held at least 8 hours before the PEG procedure; UFH infusion should be discontinued 4-6 hours before PEG and can be restarted after 6 hours of PEG tube placement [42]. Another observational study by Richter-Schrag et al. reported that patients with INR values greater than 2 on therapeutic anticoagulation have no elevated risk of bleeding during PEG placement but a cut-off value for supra-therapeutic INR was not mentioned [47].

Therefore, in summary, NSAIDs do not need to be withheld prior to PEG placement and may continue immediately after. Similarly, based on the literature, aspirin does not require cessation prior to PEG and may continue after. Clopidogrel should be held before the procedure, but can be resumed immediately after. Lastly, anticoagulation with heparin, LMWH, and coumadin can be managed as suggested above. Following PEG, coumadin can be resumed the evening of the procedure.

Management of Antibiotics

PEG placement is a interventional endoscopic procedure practiced under clean-contaminated conditions and may result in wound infections due to prior colonization of the skin or bacterial colonization from the upper aero-digestive tract [48]. Administration of antibiotics prior to PEG placement is safe and decreases vulnerability to infections even in high risk populations (e.g., old age, compromised nutritional intake, immunosuppression, and diabetes) [49]. Although pre-PEG antibiotic prophylaxis is highly recommended, continuing any antibiotics after placement of the PEG tube is not necessary and generally not practiced unless the patient requires the antibiotic for another etiology (pneumonia, sepsis).

CONCLUSION

PEG placement is a safe procedure with post-procedure mortality being less than 1% [50]. It has become the preferred method for enteral feeding in patients who need nutritional support with an intact gastrointestinal tract. Many complications that arise after placement can be prevented with appropriate post-procedure care and if they occur, appropriate care can permit effective management. All providers should be trained on post-PEG care to enable safe enteral nutrition support for the patient with long-term PEG placement.

EDITOR'S COMMENT

This chapter provides the necessary information for safe management of patients following enteral access. Without appropriate care of the tube and feedings, patient morbidity and mortality can be greatly increased. It is routine that PEG patients have limited follow-up with the endoscopist after the procedure so appropriate instructions for the nursing staff is vital including the cues requiring immediate physician evaluation. Chapter 138

PREVENTION OF PERISTOMAL PEG INFECTION

***Iruru Maetani**, MD**

Toho University Ohashi Medical Center, Tokyo, Japan

INTRODUCTION

Since its clinical introduction by Ponsky and Gauderer, percutaneous endoscopic gastrostomy (PEG) has become a widely used method of maintaining enteral nutrition, particularly for patients with swallowing disturbances [1, 2]. PEG plays an important role in creating a nutritional access route, especially for patients who require enteral nutrition for long periods of time. A meta-analysis of randomized comparative studies showed that PEG has a lower probability of intervention failure than conventional nasogastric tube feeding, and is therefore considered the preferable method [3]. Compared with operative gastrostomy, PEG is associated with fewer major complications and decreased procedure-related mortality [4]. Nevertheless, other complications remain a problem, particularly local and systemic infection, of which peristomal wound infection is the most common with an occurrence rate of 3%–30%. [5, 6].

Gottlieb et al reported that gastrostomy tubes are colonized by *Candida* species, probably of oral origin, that have made their way into the stomach [8]. There is also concern that introduction of a gastrostomy tube that is pulled out through the abdominal wall to the outside carries a great deal of potentially infectious organisms with it. Thus, PEG stomas are assumed to have the potential to be contaminated by oropharyngeal bacteria. In aged and/or frail patients indicated for this procedure, peristomal infection may pose critical, sometimes life-threatening problems, such as abscess formation (Figure 1), necrotizing fasciitis (Figure 2), and peritonitis. Measures to prevent peristomal infection are critical. This chapter provides a broad overview of preventive measures for peristomal wound infection associated with PEG tubes.

ROUTINE ANTIBIOTIC PROPHYLAXIS

The role of antibiotics in the prevention of peristomal infection has been extensively investigated [9-19]. Most studies have claimed that antibiotic prophylaxis is significantly effective in preventing peristomal infection after PEG placement, although a few reports have failed to show efficacy [9, 12]. Prophylactic antibiotics may be helpful in reducing peristomal infection in patients undergoing percutaneous radiologic gastrostomy [20]. Several meta-analyses and systematic reviews of randomized controlled trials evaluating the use of prophylactic antimicrobials during PEG-tube placement also support the benefits of antibiotic prophylaxis in preventing peristomal infection [21-24]. A pooled analysis of 12 trials (1271 cases) of prophylactic antibiotics demonstrated a statistically significant reduction in the incidence of peristomal infection (9.4% vs. 24.2%, odds ratio [OR] 0.36, 95% CI 0.26–0.50). Subgroup analysis of studies which compared intravenous antibiotics with placebo (eight trials; 586 cases) also found significantly fewer infections in patients treated with antibiotics (11.6% vs. 27.3%, OR 0.34, 95% CI 0.22–0.53). Another subgroup analysis assessing only studies comparing systemic antibiotics with no intervention (three trials; 613 cases) also

showed significantly fewer infections in patients treated with antibiotics (5.2% vs. 20%, OR 0.30, 95% CI 0.17–0.53) [24].

A meta-analysis of costs in seven published prospective randomized placebo-controlled trials showed that antibiotic prophylaxis led to an expected cost savings of 76.72 US dollars per PEG procedure [25].

At present, the American Society for Gastrointestinal Endoscopy (ASGE), the European Society of Gastrointestinal Endoscopy (ESGE) and the British Society of Gastroenterology (BSG) recommend the use of antibiotic prophylaxis prior to PEG placement in all patients [26–28]. ASGE guidelines state that parenteral cefazolin should be administered 30 minutes before PEG tube placement, while BSG guidelines mention that patients should receive a single dose of intravenous (IV) co-amoxiclav (amoxicillin-clavulanic acid) during the hour before the PEG placement procedure [26, 28]. Cefuroxime is an alternative, but should be avoided in regions with a high incidence of *C. difficile* infection or infections due to extended-spectrum β -lactamase-producing organisms.

A Taiwanese group evaluated the relationship between respiratory infection and peristomal infection. Patients with respiratory infections had an increased risk of peristomal infection after PEG placement. They found that patients with PEG-site infection were more likely to have a positive sputum culture than those without (63.3% vs. 14.6%, $P < 0.001$). The authors concluded that appropriate prophylactic antibiotics should be selected to cover the microorganisms isolated from the sputum of each patient [29].

A randomized study indicated that 20 mL of co-trimoxazole solution deposited in a newly-inserted PEG catheter is at least as effective as intravenous cefuroxime prophylaxis before PEG in preventing wound infection [30].

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS* PATIENTS

With its increasing prevalence of colonization in hospitalized patients, methicillin-resistant *Staphylococcus aureus* (MRSA) is emerging as a major pathogen in PEG site infections [31–33]. Those patients who are colonized may require MRSA-specific adjuncts to prevent PEG site infections. Currently recommended antibiotic prophylaxis regimens using cephalosporins may have diminishing effectiveness against MRSA. Patients with prior MRSA colonization are at a significantly higher risk of developing symptomatic MRSA infection of the PEG site [34, 35].

Rao et al reported that decontamination and glycopeptide prophylaxis are effective in preventing PEG-site infections with MRSA [36]. Horiuchi et al reported that oropharyngeal decolonization of MRSA with intranasal application of mupirocin, inhalation of arbekacin, and oral trimethoprim/sulfamethoxazole can reduce peristomal infection from pull-through PEG insertion [37]. A similar study from the United Kingdom showed that MRSA screening before PEG placement and subsequent decontamination and prophylactic IV teicoplanin in patients testing positive can decrease the incidence of MRSA wound infection [37]. The decontamination procedure involved daily skin decontamination with 2% triclosan shampoo washes for 5 days and nasal treatment with mupirocin ointment 8 hours prior to PEG insertion.

In a study evaluating the overall efficacy of antimicrobial prophylaxis, none of 51 patients receiving co-amoxiclav or cefotaxime (if penicillin-allergic) were found to have MRSA on wound swabs, whereas MRSA was found in nine of 48 patients receiving placebo [18]. This result may imply that co-amoxiclav has a prophylactic effect against MRSA. However, baseline MRSA status was not identified in this study. Further, although co-amoxiclav has significant *in vitro* activity against some strains of MRSA, there is no evidence of significant clinical activity against MRSA, and it is not among the antibiotics recommended for MRSA infection [39-41].

In general, standard antibiotic prophylaxis according to guidelines may not be appropriate due to the increased prevalence of resistant organisms [42]. Prevention of peristomal infection may require procedures such as decontamination of resistant organisms before PEG placement [36].

LOCAL STERILIZATION OF THE OROPHARYNX

Reducing nasopharyngeal flora using antiseptic agents prior to PEG placement appears to be an effective means of reducing the risk of infection associated with the procedure [6]. Grant et al used antibiotic-impregnated lubricating ointment before pulling the tube through the mouth to prevent PEG-site infection [43]. To avoid peristomal infection, Deitel et al suggested an antiseptic gargle where possible, or preparation of the oral cavity with povidone-iodine-moistened packing before introducing the gastroscope [44]. Other authors have recommended that in addition to antibiotic prophylaxis, patients should gargle with povidone-iodine, and have their faces painted with povidone-iodine and fully draped prior to PEG placement [45]. The efficacy of these methods, however, has not been proven in prospective trials, moreover the maneuvers may be impractical in patients who are at a high risk of aspiration. Oral surgeons have known for many years that topical antimicrobials applied to the oral cavity and pharynx prior to dental procedures reduce the number of bacteria, the incidence of bacteremia, and related infectious complications [46-48]. However, these measures need to be tested in a prospective randomized trial for PEG placement.

Bypassing the Oropharynx (PRG/PEG with the Introducer Method)

The introducer technique may carry a lower risk of peristomal infection compared with pull-through or push-over wire techniques, since the PEG catheter does not pass through the oropharyngeal cavity during placement. Based on their study of fungal organisms from the oral cavity, stomach, and gastrostomy tubes, Gottlieb et al suggested that gastrostomy tubes are probably colonized by oral organisms that have migrated to the stomach [8].

A review article assessing over 5000 cases revealed that percutaneous radiologic gastrostomy (PRG) was associated with significantly fewer major complications (e.g. wound-related problems, aspiration, and peritonitis) than PEG (mostly pull-through technique) [49]. Presumably, the lower risk of peristomal infections with PRG is attributable to the direct insertion of the feeding catheter into the opacified stomach under sterile conditions without the need for passage of a catheter or other instrument and its accompanying flora from the

oropharynx to the stomach and through the abdominal wall and skin. In a prospective but nonrandomized study, local wound infection was more common in PEG than with PRG (18% vs. 2%, $P = 0.008$) [7]. No randomized comparison of PEG and PRG has yet been published. Two articles suggested that peristomal infection was more frequent with PRG than with PEG; however, these studies appear to have been subject to selection bias, as the PRG group included more cancer patients, who are often at higher risk of infection from immunosuppression [50, 51].

In 1984, Russell and colleagues reported a percutaneous endoscopic gastrostomy performed by pushing an introducer contained in a pacemaker lead peel-away sheath over a guidewire directly into the stomach [52]. A study comparing the pull-through technique with introducer-PEG placement using Russell's technique reported that no peristomal infections occurred in the introducer group (0% for introducer vs. 21% for pull) [44]. Later, an introducer technique which used a large-caliber trocar became available, allowing larger-bore gastrostomy tubes to be inserted. Several reports on this procedure have also indicated a low rate of peristomal infection (0–3.7%), as the gastrostomy tube does not pull oropharyngeal flora across the abdominal wall [53–56].

Many studies have compared the introducer technique with the pull and push techniques, with varying results. A randomized controlled trial assessing the occurrence of peristomal infection following introducer PEG placement with or without prophylactic antibiotics revealed that this technique can be safely performed without them, even in patients who are at high risk of peristomal infectious complications (e.g., those with advanced oropharyngeal malignancies) [19].

Several other reports have compared various PEG-with-introducer methods with the conventional pull or push methods. A retrospective comparison of the push and introducer methods for PEG placement found no difference in the occurrence of peristomal infection [57]. A previously mentioned study suggested that the introducer method was faster and was associated with fewer peristomal infections than the pull method (0% vs. 21%, respectively). Another comparative study revealed similar results (1.9% vs. 36.5%, $P = 0.001$) [58]. A prospective randomized trial comparing the Russell method with the pull method found that the rate of peristomal infection was significantly lower with the introducer method than the pull method (0% vs. 31%, respectively; $P = 0.00094$) [59]. A recent retrospective study found no significant difference between pull-type and introducer-type PEG insertion with respect to acute wound infection rate (≤ 7 days after PEG insertion) [60]. A significantly low rate of peristomal infection (2.6%) was found for the pull technique, while the rate of peristomal infection for the introducer group was 1.7%, which is comparable to previous studies.

One of the drawbacks of PRG or introducer PEG, including the trocar method, is that they are restricted to the use of only small caliber catheters. To make up for this shortcoming, a modified introducer technique which allows direct placement of a larger catheter has been developed. For this technique, two prospective randomized studies and two retrospective studies comparing the modified introducer with the pull technique showed a lower incidence of peristomal infection in the modified introducer group, with the exception of one randomized study, in which peristomal infection was less likely in the modified introducer group although not to a statistically significant extent (12.9% vs 23.3%, $P = 0.3354$) [61–64].

A meta-analysis which included both standard introducer and modified introducer techniques analyzing six comparative and 10 observational studies (2336 cases) concluded

that the pull technique appears to be associated with a significantly higher risk of infection than the introducer technique [65]. In the comparative studies, the risk of infection was significantly higher with the pull technique (OR 13.0; 95% CI, 4.6–36.8; $P < 0.0001$). The observational studies also reported higher infection rates with the pull technique (10.7%; 95% CI, 4.9–21.8 for the pull technique vs 0.9%; 95% CI, 0.2–4.5 for the introducer technique).

As stated above, the introducer technique, which avoids passage of the PEG tube through the oropharyngeal cavity before crossing the abdominal wall, appears reasonably effective in reducing the occurrence of peristomal infection. However, the pull method has long been the gold standard of PEG placement, and most endoscopists are familiar with the technique. In Japan, in contrast, standard and modified introducer techniques together accounted for more than half of all PEG placement procedures in 2013 [66].

OVERTUBE USE

Sharma et al advocated the use of an overtube (Figure 3) during the PEG procedure in head-and-neck cancer patients to prevent implantation of cancer cells at the PEG site [67]. Takahashi et al first reported the clinical application of an overtube during PEG placement [68]. They showed that use of an overtube such as that used for endoscopic variceal ligation (EVL) helps to simplify the second insertion of the endoscope to confirm positioning of the internal bumper. The authors assumed that this procedure can lower the risk of peristomal infection, as it avoided contact of the catheter with the oropharyngeal cavity [68].

To confirm this assumption, Maetani et al conducted a randomized controlled trial to compare the occurrence of PEG-site infection between PEG placement with and without an overtube, and found that the use of an overtube lowered the risk of peristomal infection (5% vs. 33%, respectively; $P = 0.0029$) [69]. This procedure has the additional advantage of allowing the use of many different sizes and models of PEG tube. Although no overtube-related complication were encountered in the study, complications associated with overtube-related pinch injury during EVL have been reported, indicating the need for caution in overtube insertion [70]. A recent study evaluated the feasibility and safety of the overtube method for PEG placement in patients with head and neck cancer, employing a new overtube featuring a tapered tip designed to protect against mucosal damage [71]. In this study, peristomal infection occurred in only 5.7%, which is comparable to the aforementioned study using standard overtubes [69]. There also were no cases of overtube-related adverse events such as implantation of cutaneous metastases during a median follow-up period of 16 months [67].

Figure 3. Gastric length esophageal overtube.

Thus, use of an overtube appears to be beneficial in reducing the transmission of bacteria or tumor cells from the oropharyngeal area to the PEG site. These results suggest that the use of an overtube may be beneficial in reducing the risk of PEG-associated peristomal infection when using a peroral route. Overtubes can be placed in patients receiving conscious sedation only, but occasionally the discomfort associated with placement may require general anesthesia. The risk/benefit ratio of their use in this circumstance should be considered by the endoscopist.

COVERED PEG

Suzuki et al evaluated the efficacy of a covered PEG kit in preventing peristomal infection [72]. The kit (Nutrex Gastrostomy Tube, Nippon Sherwood Medical, Tokyo, Japan) contains a 20 Fr PEG catheter preloaded in a narrow overtube. The overtube is easily passed through the oropharynx to the stomach using the pull technique and once there the overtube is pulled retrograde off of the PEG and removed from the mouth (Figure 4). They reported that use of this kit was associated with significantly fewer peristomal infections than uncovered PEG insertion with the same pull technique (2% vs. 33%, OR 0.05; 95% CI 0.02–0.13) [72]. The overtube group also had significantly lower body temperature, white blood cell counts, and C-reactive protein levels. Although the entire pathway from the mouth to the stomach was completely covered by the overtube using this device, this method is disadvantaged by its incompatibility with other PEG catheters.

Figure 4, Inserting a covered percutaneous endoscopic gastrostomy (PEG). A) Needle and sheath are inserted through the abdominal wall and grasped with a snare in the stomach. B) Needle is removed from sheath. C) Guidewire is inserted through the sheath. D) Endoscope is removed, bringing the guidewire with it. E) Covered PEG is connected to the guidewire. F) Inserting covered PEG tube along with guide wire. G) PEG and overtube are pulled into the stomach. H) PEG tube is pulled through the abdominal wall. I) PEG tube now free from the covering sheath. J) The covering sheath is removed via the oral cavity. K) Confirm the position of PEG by endoscopy.

ANTISEPTIC USE AT THE PEG SITE

Radhakrishnan and colleagues showed that a single application of povidone-iodine local antiseptic spray combined with systemic antibiotic prophylaxis at the time of PEG insertion reduces the incidence of PEG site infection [73]. Among three groups, an antibiotic group (A), antiseptic spray group (B), and combined group (C) ($n = 34, 28$ and 34 , respectively), MRSA was not isolated in any patient in group (C), but was isolated in four patients from group (A) and two from group (B).

GASTROPEXY

Gastropepy is often performed during PEG insertion, particularly in skin-to-stomach PEG placement methods such as the standard and modified introducer techniques [7, 19, 63, 74]. Campoli et al assessed the rate of peristomal infection between two different gastropepy techniques [75]. All patients underwent the introducer technique without use of antibiotic prophylaxis. One group underwent gastropepy with two straight needles, one having a strand of nylon suture and the second having a loop made with another nylon suture. A polypectomy snare is introduced through the endoscope and used to bring the loose suture through the loop. After capture, the whole set is taken out so as to obtain a U-shaped suture. The other group underwent gastropepy using a long curved needle to place two suture stitches, which transfixed the abdominal and gastric walls. Gastropepy performed with a curved needle was associated with a lower rate of infection than gastropepy with two straight needles (0.2% vs. 2.8%, $P = 0.03$). The higher rate of peristomal infection in the latter group is presumably due to contact of the endoscopic accessories with the sterile suture, and the complexity of the procedure. However, a gastropepy device which enables suture stitching without the use of an endoscopic accessory device is now commercially available [19].

A retrospective study in Japan indicated that PEG with gastropepy markedly reduced peristomal inflammation compared with PEG without gastropepy [76]. When evaluation was confined to patients who underwent pull-type PEG placement, however, no statistically significant difference between procedures with or without gastropepy was seen.

MISCELLANEOUS ADJUNCTS

Kuo and colleagues conducted a randomized study to determine whether 14-day discharge before PEG placement reduced the rate of peristomal infection, following previous findings that outcomes after PEG placement were better in ambulatory than hospitalized patients [77-79]. The study concluded that a 14-day grace period after discharge, before PEG placement, may decrease peristomal infection, length of hospital stay after PEG, and the need for antibiotics.

Fagundes et al retrospectively analyzed the association of peristomal infection with the extent of the skin incision and use of prophylactic antibiotics. Peristomal infection was less common in patients with 5 mm incisions than those with 10 mm incisions (2.2% vs. 12.4%, $P = 0.01$), while there was no association with prophylactic antibiotics ($P = 0.3$) [80].

Blumenstein and colleagues evaluated the efficacy of glycerin hydrogel (GHG) wound dressing, which possesses more effective antimicrobial properties than dry dressings [81]. Their randomized study revealed a significantly reduced rate of peristomal infection at 7 days in the GHG group (14.7% vs. 47.05%, $P < 0.005$). In addition, dressing changes with the GHG wound dressing were five times less frequent than with the traditional dressing. Cost-effectiveness analysis for the first month revealed a net cost saving of about 425 US dollars (310 €) per patient in favor of the GHG dressing.

Another study found that an activated charcoal dressing with silver (ACTISORB® Silver 220, Johnson & Johnson Medical, New Brunswick, NJ, USA) used for post procedural wound care may be helpful in reducing peristomal infection [82]. These results are preliminary, although the dressing's antimicrobial effect was demonstrated in a previous *in vitro* study [83].

Japanese researchers evaluated the relationship between gastric acidity and the occurrence of PEG site infection [84]. Results showed a trend toward a higher pH level in the infected group (4.05 ± 2.61 vs. 3.09 ± 1.86 , $P = 0.07$). In patients negative for MRSA in the oropharynx, the pH level was significantly higher in the infected group (5.05 ± 2.55 vs. 3.06 ± 1.83 , $P = 0.0019$). In this study, the median pH of ten patients with peristomal infections caused by MRSA was 2.96. MRSA might be unaffected by gastric acidity, presumably due to acquired resistance to low pH. On the basis of these results, the authors suggested that an H₂-receptor antagonist or proton pump inhibitor should not be administered during the course of PEG placement to reduce the risk of PEG site infection.

Aside from said procedures, basic tube management procedure is quite important, despite the empirical manners. The external bumper should be 1-2 cm away from the abdominal wall to avoid excessive tension between internal and external bumpers which may cause impaired vascular perfusion of peristomal site and gastric ulceration. These may be associated with occurrence of peristomal infection and/or buried bumper syndrome. In one or two days after PEG placement, possible significant tissue edema at PEG-stoma may lead to excessive tension between both bumpers. In such case, external bumper should be moved in keeping away from the abdominal wall.

CONCLUSION

Peristomal wound infection is the most common complication associated with PEG procedures. Preventing wound infection is important, as many PEG patients will have poor healing due to associated malnutrition. Prophylactic antibiotics are effective in reducing the risk of peristomal infection, as has been suggested in some guidelines. However, MRSA and other resistant organisms have emerged as major pathogens in peristomal infection, and alternative procedures other than standard prophylactic antibiotics may be necessary. Possible effective measures include decontamination of the oropharynx and skin prior to PEG placement, but these remain uncertain. A standardized procedure to prevent MRSA-related infection needs to be established. In addition, PEG with an introducer method, use of the pull method with an overtube, or antiseptic use at the PEG site appear to be beneficial in reducing the risk of PEG site infection.

EDITOR'S COMMENT

As eloquently outlined in this chapter, infection prevention during PEG extends well beyond the prophylactic dose of antibiotics. There are a wide array of maneuvers applicable to PEG placement that have been shown in small studies to reduce the risk of infection. What is not always delineated in these studies, however, is the cost/benefit ratio of the intervention. The number needed to treat and the relative risk reduction of these interventions is not always clear. Consideration must be given by the endoscopist to the added cost and added risk associated with these adjunct maneuvers before widespread implementation should be considered. (EMP)

Chapter 139

ACUTE COMPLICATIONS OF PEG

Lava Y. Patel, MD and Michael B. Ujiki*, MD

North Shore University HealthSystem, Evanston, IL, US

INTRODUCTION

Advancements in laparo-endoscopic techniques over the past 30 years have led to significant improvements in enteral access with regards to procedure-related morbidity and cost when compared to previous open techniques [1, 2]. Percutaneous endoscopic gastrostomy (PEG) is now of the most commonly performed upper endoscopic procedures. It has been shown to be safe, cost-effective, and with continued high rates of success (>95%), PEG is the preferred method of gastrostomy insertion [2-7].

Recent studies show that overall complication rates following PEG range from 6.5-39.0% [8-13]. This wide range is due to differences in study populations, techniques, and outcomes reported. Minor complications, which account for 4.6-23% of all complications following PEG, can broadly be thought of as self-limiting, include local wound infection, tube malfunction, leakage, peristomal pain, and fever [12, 14]. Major or severe complications vary in definition, but include potentially life-threatening ones which require further intervention. These complications include aspiration, perforation, peritonitis, thromboembolic events, sepsis, necrotizing fasciitis, hemorrhage, and both solid organ and hollow viscus injury. The incidence of major PEG complications has typically been reported at 1%-4%, but can be as high as 7%-10% [3, 12-17].

Table 1 summarizes reported complications associated with PEG. Minimizing complications begins with prevention. Appropriate initial assessment with proper patient selection (see Chapter 2), preoperative management (see Chapter 3) and sound technique (see Chapters 7-11), are well recognized ways to minimize complications]. In this chapter we discuss commonly described acute complications associated with PEG tube placement and provide diagnostic and therapeutic management options.

Leak and Peritonitis
Necrotizing fasciitis
Hemorrhage
Hollow viscus injury
Liver/Spleen Injury
Buried Bumper Syndrome
Tumor tract seeding
Thromboembolic Events

DEATH

Regardless of technique type, procedure-related mortality for PEG is low (0%-3%) [8, 12, 18-21]. However, most major complications can be attributed to technical errors during initial insertion and PEG-related complications themselves have been shown to be independent predictors of hospital mortality [22, 23]. Thirty-day mortality rates range from 0%-18.4% [12, 15, 17, 21, 24-26]. Multicenter data has shown low albumin and high C-reactive protein (CRP) levels to be predictive of 30-day mortality [27, 28]. Certain populations have been shown to be at higher risk of PEG-related mortality, including cancer patients and geriatrics [3, 17, 29]. In a systematic review and meta-analysis of 2379 head and neck cancer patients undergoing percutaneous gastrostomy, Grant et al. observed overall mortality of 2.2%, but the mortality rate in head and neck cancer patients was found to be higher than that in mixed patient populations [3]. Overall mortality has been reported as high as 51% in PEG patients and is usually due to associated comorbidities [30]. Early diagnosis and management of post-PEG complications is of utmost importance and can reduce the already high mortality seen in this vulnerable population [31, 32]. Table 2 summarizes reported risk factors for morbidity and mortality following PEG.

Pneumoperitoneum

Routine chest or abdominal radiographs after uncomplicated PEG procedures is not common practice at many institutions, although some authors have recommended that it should be [33]. However, because the many PEG patients are critically ill, imaging may frequently be indicated for other reasons (i.e., respiratory distress, fever work-up, daily chest X-ray for intubated patients) and often leads to findings of free intra-peritoneal air [34]. Possible etiologies of PEG-associated pneumoperitoneum include the introduction of air during gastric insufflation, needle puncture and tube placement, tube malposition (dislodgement or intra-peritoneal placement) or hollow viscus injury. Hollow viscus injury (including colon, small bowel or stomach) is uncommon although several reports and case-series have described injuries to each. Inadvertent esophageal injury has also been reported

[8, 35]. These injuries, along with tube mal-position, are discussed later throughout the chapter.

Pneumoperitoneum following PEG is frequently encountered (Figure 1), with earlier reported rates ranging from 23.3 -55.6% and can last up to 4 weeks after the procedure [36, 37]. This initial high rate may be explained by the use of room air insufflation in these earlier studies. Carbon dioxide (CO₂) insufflation, long used in laparoscopic surgery, has been shown to decrease post-procedural pain, flatus, and bowel distention and is now commonly used for endoscopic procedures [38]. CO₂ is a highly diffusible, non-combustible gas that is rapidly absorbed and excreted and can be expected to be fully reabsorbed within the first 24 hours [39]. A recent randomized trial compared pneumoperitoneum rates between CO₂ and air insufflation using computed tomography (CT) imaging at 24 hours post-PEG, and found that pneumoperitoneum was only present in patients in the room air group [24]. Literature over the last decade has shown the rate of CO₂ pneumoperitoneum to be closer to 0-16% [34, 40-42].

In the general population, free air is indicative of hollow viscus injury and has typically warranted exploratory laparotomy. However, interpreting the clinical significance of such findings in PEG patients can be challenging. In the vast majority of cases, benign pneumoperitoneum will be encountered [34]. Unless accompanied by peritonitis, sepsis, or hemodynamic instability, no further work-up is typically necessary in these situations. Clinically significant pneumoperitoneum can be found in up to 15% of cases [34]. Free air may sometimes be the only clinical sign of perforation (misplaced tube; organ injury) as peritoneal irritation may go unnoticed in diabetics, patients receiving antibiotics, steroids, or those with altered consciousness. A “silent perforation” may also occur if retroperitoneal organs (i.e., descending colon) are injured and can lead to a delay in diagnosis.

The presence of free-air within 24 hours of PEG should not be unexpected. Patients found to have free-air on plain radiographs 24-48 hours after PEG without signs of peritonitis or clinical decline can generally be observed and plain films repeated in 24 hours. When repeating plain films, we recommend obtaining at least two views. The combination of upright lateral chest and lateral decubitus imaging increases the sensitivity of detecting pneumoperitoneum to 98% [43]. If free-air is again seen, then additional evaluation may be warranted (see below). If at any point pneumoperitoneum is encountered in a patient with signs of peritonitis and/or hemodynamic instability, time should not be wasted obtaining further imaging and the patient should be surgically explored.

Free-air encountered 72hr or more after PEG, should raise clinical suspicion in the typically debilitated patients undergoing this procedure as a missed hollow viscous injury which can be devastating. Even for clinically stable patients, further evaluation with a CT scan is a prudent decision in most cases. CT is considered the gold standard and more sensitive for identifying pneumoperitoneum than plain radiographs [24]. In a study describing PEG-induced pneumoperitoneum, CT revealed the presence of free air in 6 out of 10 patients who had no evidence of pneumoperitoneum on previous chest x-ray [44].

In a retrospective review of over 700 PEG cases, Blum et al. found pneumoperitoneum on imaging in 5/6 patients who had undergone exploratory laparotomy for a PEG-related complication [34]. They recommended that any patient with free air on plain radiograph, even those without peritonitis, undergo CT evaluation and if free fluid is seen (Figure 2) surgical exploration be performed. With the lack of published guidelines, it is important to approach each patient with free-air on an individual basis. Knowledge of insufflation gases, timing of

pneumoperitoneum, relevant clinical findings, and when to obtain further imaging can better equip clinicians to handle this diagnostic dilemma.

Figure 1. Pneumoperitoneum grades following PEG A) Small grade pneumoperitoneum (<2 cm tall column of air under the diaphragm). B) Moderate grade pneumoperitoneum (2-4 cm tall column of air under the diaphragm). C) Large grade pneumoperitoneum (>4 cm tall column of air under the diaphragm). Reproduced from Park et al with permission [40].

Figure 2. Post-PEG intraperitoneal leak. Free air (arrow) and an air fluid level (arrowheads) are noted on a CT obtained for moderate grade pneumoperitoneum 48 hours after a PEG was performed with CO₂ insufflation. The patient subsequently underwent a laparotomy and Stamm gastrostomy.

Leak and Early PEG Dislodgement

Accidental tube dislodgement is a well published and frequently encountered complication following PEG, occurring in up to 32% of cases [10]. The gastro-cutaneous tube tract begins to mature at 1-2 weeks and is well developed by 4-6 weeks [33]. Inadvertent tube removal can occur either early (before the fistula tract has fully matured) or late (several weeks to years following initial placement), and the timing of such has different implications. Here we will discuss diagnostic and management strategies for early tube dislodgement. Late dislodgement after tract maturity will be discussed in the Chapter 19.

Figure 3. Post-PEG transabdominal leak. Flow of fluid (arrowheads) and air bubble (arrow) were noted on postoperative day 2.

Figure 4. Post-PEG leak into the pre-peritoneal space in a patient with clinical signs of abdominal wall erythema and fluctuance. A) Gastrostomy bumper correctly positioned in the body of the stomach with air surrounding the tract. B) Air and fluid contained within the abdominal wall.

Differences in techniques, catheters, and fastening devices may explain the wide range of rates reported. The most commonly used PEG tubes are designed with collapsible inner bumpers or balloons to facilitate easy removal with external traction. This design also carries with it the risk of inadvertent removal especially in the confused, mentally-altered patients who often require them. Other causes of leakage include excessive tension leading to gastric necrosis, excessive movement of the tube and malnutrition. Loss of stomach opposition to the anterior abdominal wall then leads to leakage of gastric contents from the gastrostomy site into the peritoneal cavity or externally around the tube (Figure 3). Clinical findings along with degree of dislodgement should dictate further work-up and management.

Clinical signs of tube leak or dislodgement include erythema, induration, and fluctuance (Figure 4). The tube itself should be interrogated, looking for peri-tubal leakage, difficulty flushing/aspirating, or difficulty manipulating tube position. If there is any evidence of the above, enteral feeding should be discontinued, a decompressive naso-gastric tube (NGT) inserted, and broad-spectrum antibiotics initiated [1]. Cases of *Candida* peritonitis have been reported and empiric anti-fungal coverage should also be considered [45]. Peritonitis should

be suspected in patients with abdominal pain, tenderness (more than just insertion site discomfort), fever, or leukocytosis and immediate surgical consultation obtained.

Some patients may have clinical findings but no evidence of peritoneal irritation. In these situations, a tube or tract fistulogram may be useful. Water-soluble contrast can be injected into the PEG catheter of patients with partial tube dislodgement or into the stoma site of patients with complete removal. Subsequent abdominal radiographs can delineate tract anatomy and display gross or contained leakage within the peritoneal cavity. For partially removed tubes, tract continuity with the gastric lumen, without contrast extravasation, means that the tube has been slightly pulled out. If complete removal is encountered and the stoma site is patent, contrast injection into the tract itself can be performed. The contrast injection may reveal partial disruption of the tract (Figure 5). In patients with healed stomas sites, avoid attempts at dilation. In this case, a CT abdomen/pelvis with oral contrast should replace the fistulogram. CT will provide similar information with regards to extravasation and more details regarding tube location and potential organ injury. Some authors have reported the presence of hepatic portal venous gas on CT imaging obtained in patients who were found to have gastrostomy leak [46, 47]. A recommended management algorithm is shown in Figure 6.

Replacing tubes after removal can potentially lead to further complications. Best practice should be to never blindly re-insert a PEG tube if it has been completely pulled out within 7 days of placement as the fistula tract may not have fully matured. Endoscopic replacement with direct visualization is the safest means for replacing a tube during this period. Diagnostic endoscopy should be performed to visualize gastrostomy site and other potential pathology. A new PEG can be inserted distally and the original site can be closed using endoscopic clips or an endolumenal suturing device (Figure 7) [48]. See Chapter 20 for further discussion on endoscopic management of early tube dislodgement.

Early tube pull can also be managed with basic laparoscopy. Laparoscopy obviates the need for a potentially time-consuming fistulogram in patients who may need surgical exploration anyway, as it provides direct visualization of entire intra-peritoneal cavity. The ability to assess the posterior gastric wall, duodenum, small bowel and colon adds the benefit of ruling out inadvertent injury to them. The gastrostomy can either be repaired primarily with intracorporeal suturing or can be converted to a Stamm gastrostomy (Figure 8) [1].

Figure 5. Gastrostomy track disruption after early PEG dislodgement. A) Partial Disruption – injection via the PEG tract demonstrates contrast within the body of the stomach (arrow), but also free leak of contrast into the peritoneal cavity (arrowheads). B) Complete Disruption – injection via PEG demonstrates only free intraperitoneal contrast with no filling of the gastric body.

Figure 6. Proposed algorithm for the management of early PEG dislodgement.

Tube dislodgement, occurring at any time, increases patient morbidity and mortality and management of these complications is associated with significant healthcare costs (readmissions, length of stay and resource utilization) (Figure 9). Educating patients, caregivers, and nursing staff about the potential complications can help reduce early tube pull and leakage. As clinicians, being able to identify at risk patients and using certain preventive strategies can minimize these occurrences and healthcare burden (Table 3).

Table 3. Measures to prevent early tube dislodgement in high risk patients

Procedural	
Additional gastropexy	Maintains gastric apposition even if pre-mature removal occurs
Use mushroom tip or button catheters	Not as easily removable
Post-Procedural	
Confirm integrity of external fixation	Address security of sutures or appliances daily
Daily tube check	Ensure original position maintained and no undue tension
Ensure comfort with appropriate narcotic use and tube hygiene	Minimize pain/skin irritation that may cause patients to tamper with tube
Physical barriers	Use of soft restraints or abdominal binder

Figure 7. Endoscopic mucosal closure devices. A) Over the scope clip (OVESCO OTSC™). B) Through the scope clip (Boston Scientific Resolution Clip). C) Endoscopic suturing device (Apollo Overstitch™).

Figure 8. Leaking PEG converted to Stamm gastrostomy with the use of 4 trans-abdominal sutures [1]. Reprinted with permission from B. Todd Heniford, MD.

Hollow Viscus Injury

Inadvertent bowel injury is typically rare and therefore its true incidence is difficult to define. Based on several case reports, inadvertent injury to bowel occurs in approximately

1.3% of cases. Free perforation or enterocutaneous fistula formation (including gastro-enterocutaneous) can manifest in the early post-operative period (up to 2 weeks) [49]. Injury to small bowel also very rare but may occur for many of the same reasons as colonic injury. Causes may include inadvertent initial placement, compression necrosis and migration of catheter tip and retained flange with subsequent perforation [50]. Through and through penetrating injury to the mesentery during initial placement resulting in small bowel volvulus and obstruction has also been described [51].

Colonic perforation is one of the most serious complications and can be fatal if missed. The transverse colon typically lays antero-superior to the stomach, placing it in harm's way during peg (Figure 10). The sigmoid colon may loop anterior to the stomach in patients with colon motility disorders, colonic distention or altered body habitus (Figure 11).

Figure 9. CT scan of a patient following her third early PEG dislodgement. A) PEG bumper is located in a subcutaneous position with surrounding soft tissue stranding and air. B) Gastrointestinal T-Anchors prevented the gastrotomy from falling away from the abdominal wall preventing free intraperitoneal leak.

Figure 10. Transverse colon injury from PEG placement. Flat plate X-ray demonstrates contrast filling the transverse colon. Reproduced from Friedmann et al with permission [59].

Figure 11. Sigmoid colon injury from PEG placement. A) CT scan demonstrates severe abdominal distortion from scoliosis. B) Flat plate X-ray demonstrates contrast filling the sigmoid colon and rectum when injected into the gastrostomy tube.

Geriatric patients may be at higher risk due to lax peritoneal attachments or redundant segments of colon. Adequate insufflation allows gastric opposition to the abdominal wall while displacing the overlying colon inferiorly. Adherence to sound technique with subsequent trans-illumination and visual finger indentation minimizes the possibility of injury to colon or small bowel [53].

Although PEG has been shown to be safe in patients with previous abdominal surgery, additional preventative strategies may be necessary. Strodel described inserting a small-gauge needle from through the abdominal wall into the insufflated stomach while aspirating on the needle syringe. If air is aspirated into the syringe before the needle seen in the stomach, then there is air-filled bowel, small or large, interposed between the stomach and the abdominal wall [54]. A similar “safe-tract method” with a fluid filled syringe has also been shown decrease inadvertent bowel injury in patients with previous abdominal surgery, with misplacement being assumed if air bubbles appear in the syringe before needle visualization in the gastric lumen [55]. A second-look, with either upper endoscopy or placement of a laryngofiberscope through the inserted feeding tube can be used to confirm intra-gastric tube placement [56].

The use of image guidance to prevent complications and facilitate safe PEG placement should be considered in certain situations. CT-guidance for patients with unsuccessful endoscopic trans-illumination has been shown to be effective for PEG placement without bowel injury [57]. Sasaki et al. described the use of pre-PEG abdominal CT to identify high risk patients based on colon anatomy relative to the stomach who then underwent PEG with the use of contrast radiography of the colon and no injuries occurred in these patients [58]. Colonic compromise can occur during initial placement or at any time re-insertion or exchange is performed. Misplacement of PEG through or into the colon has been reported and the time to diagnose the injury can range from 1 day to 6months [19, 59, 60]. PEG patients are often critically ill, sedated or have altered levels of consciousness at baseline, making it is easy to miss clinical signs of perforation and peritonitis (i.e., pain, tenderness,

rebound/guarding), making early diagnosis difficult [14, 61]. There should be a low threshold of clinical concern in these high risk patients. Severe diarrhea, fecal presence within the PEG tube, or feculent drainage around the tube have all been identified as clinical signs of colonic injury and should warrant further investigation [19, 59, 60].

If a colonic injury is suspected, assess the patient for hemodynamic stability and perform a focused abdominal exam to include interrogation of the PEG tube. If the patient is hemodynamically stable, obtaining an upright CXR or lateral decubitus abdominal film can quickly identify pneumoperitoneum or changes in tube position, which may expedite surgical exploration (See pneumoperitoneum section above for further details and management algorithm). However, if clinical concern is high and findings equivocal, abdominal CT is more specific for identifying organ injury and can provide a more definitive diagnosis (Figure 12) [61]. Fistulograms are also helpful as they can be performed rather quickly at the bedside. Water soluble contrast can be injected into insertion site and portable abdominal film obtained which can show if there is intra-peritoneal extravasation, controlled leak, or inadvertent placement into bowel.

Controlled perforations in hemodynamically stable patients can be managed non-operatively. The PEG tube should be removed and a NGT placed while allowing the tract to heal. A new PEG can be attempted at a new site 7-10 days thereafter. If the patient is unstable or has signs of peritonitis or sepsis, urgent surgical exploration is warranted and exploratory laparotomy may be the most conservative approach proving quick access and full exposure. However, if the patient is able to tolerate it, laparoscopy can be performed to evaluate the extent of injury and foregoes the morbidity associated with a laparotomy incision. Surgeon experience and patient status should dictate whether or not to proceed with laparoscopic or open management. The goal of exploration, open or laparoscopic, should be to efficiently identify the injury, repair or resect injured bowel (with or without the formation of a colostomy), and perform adequate abdominal washout of enteric content [19].

Figure 12. CT scans of patients with colon injury following PEG. A) Patient 1 – contrast injected into the gastrostomy is identified in the colon (arrowheads) as is the PEG bumper. The decompressed stomach is seen posterior to the colon (arrow). B) Patient 2 – Sagittal view demonstrates PEG bumper within the body of the stomach but traversing the transverse colon as it leaves the abdominal cavity.

The need for on-going enteral nutrition should be re-assessed at this point, taking into account the patient's initial indication and current overall prognosis. When feasible, enteral nutrition is preferable because it is safer, less costly, and offers several physiologic benefits: it maintains gut flora, helps to preserve the enteral immune system, decreases mucosal atrophy, and avoids the risk of bacterial translocation into the bloodstream [62]. For patients found to have intra-colonic or trans-colonic misplacement at exploration, the original tube should be removed and NGT can be placed for gastric decompression and parenteral nutrition started post-operatively. A nasojejun tube may be placed intra-operatively and can provide enteral nutrition for up to 4 weeks. If longer term feeding or gastric decompression is necessary, a surgical gastrostomy tube can be placed at that time. Broad spectrum antibiotics should be continued post-operatively until the patient shows resolution of sepsis or infection (hemodynamically stable, afebrile, normal WBC count).

Bleeding

Recent literature from large series in the United States shows the overall incidence of bleeding following a PEG to be 2.8-3.3% [63, 64]. The American Society for Gastrointestinal Endoscopy has defined PEG to be a high-risk endoscopic procedure with a 2-2.5% risk of clinically significant bleeding [65, 66]. Patients on anti-platelet or anti-thrombotic therapy may be at increased risk of bleeding but the risk may outweigh the potential complications of stopping such medications in patients with cardiovascular or cerebrovascular diseases. See Chapter 4 for guidelines for antiplatelet and anticoagulation management. Some evidence suggests that selective serotonin re-uptake inhibitors and not anti-platelet agents increase the risk of bleeding following PEG [64].

Upper gastrointestinal bleeding (UGIB) following PEG can be due to gastric ulcers, or gastritis/esophagitis caused by iatrogenic mucosal injury [67]. Mucosal injury to upper GI tract can occur while pulling the catheter into the stomach from the oropharynx over a string or guidewire [68]. Signs of such injuries may include hematemesis, melena, positive fecal occult blood test, blood in or around PEG tube, or unexplained drop in hemoglobin.

Use of an overtube may help prevent inadvertent injury to the GI mucosa. An overtube is a sleeve-like semi-rigid plastic tube, with an inner diameter large enough to accommodate endoscopes for various procedures (Figure 13). It is intended to protect the UGI mucosa from trauma and can also reduce the risk of aspiration [69]. If suspected, patients should be stabilized, transfused with blood products as necessary and transferred to an intensive care unit for closer monitoring if necessary. Once stable, an upper endoscopy can be performed to identify the source of bleeding and hemostasis achieved with injection, topical cautery, or hemostatic clips [67]. See Chapter 20 for more information on the endoscopic management of post-PEG bleeding. For patients that have complex anatomy or obstructing upper aerodigestive cancers, endoscopic access may be obtained through the PEG tract itself [70]. All patients should be started on acid suppression therapy before the procedure, and maintained on such after it.

Bleeding from the skin incision made to accommodate the PEG tube is common and usually self-limiting or controlled with direct pressure or topical cautery. Abdominal wall and gastric wall vessels may be at risk during percutaneous needle stick. Abdominal wall vessel injury typically presents with hematoma formation [71]. Patients with portal hypertension and

coagulopathy may be at increased risk. Abdominal vessel injury may be controlled with direct pressure over the area in some cases or may require suturing of the vessel in others. Early gastric bleeding after PEG should raise concern for possible injury to the gastric arteries or their branches, which occurs in <1% of cases [72-74]. Some cases may be managed simply by pulling the tube more tightly at the skin in an attempt to increase direct pressure between the stomach and abdominal wall, causing a tamponade effect. If successful, it is important to release that tension within 48 hours to prevent compression necrosis of the gastric wall. In other cases, the bleeding may not be controlled but such maneuvers, and further intervention is needed. Successful angio-embolization of injured gastric and gastro-epiploic arteries has been described and may be the least invasive option [75]. If resources are not available or any signs of hemodynamic instability present at any time, operative exploration is warranted and can be done either laparoscopically or via laparotomy (Figure 14).

Figure 13. Overtube devices. A) Apollo OverTube™ (Apollo Endosurgery). B) Guardus™ overtube (US Endoscopy).

Figure 14. Laparoscopic view of acute bleeding from a gastric submucosal vessel following PEG placement.

Solid Organ Injury

Splenic or hepatic injury during PEG is exceedingly rare, but cases of each have been reported. Patients with hepatosplenomegaly may be at increased risk [76]. In these patients, image-guided PEG may be prudent or simply ultrasound guidance to confirm proper needle insertion into the stomach can prevent inadvertent injury.

The anatomic location of the left hepatic lobe may place it in harm's way during percutaneous insertion (Figure 15). Most inadvertent liver injuries occur during needle stick and are self-limiting. In those cases, conservative measures with serial hemoglobin checks to assess for on-going bleeding can be used. If there is any concern for ongoing blood loss, the patient should be stabilized with fluid resuscitation and/or blood transfusion and monitored in the intensive care unit. A contrast enhanced CT of the abdominal and pelvis can then be performed to further evaluate the extent of injury and for active extravasation of intravenous contrast agent. For cases in which the catheter itself is inserted and the balloon inflated within the hepatic parenchyma, significant hemorrhage can occur [77]. If the patient remains hemodynamically stable but with ongoing blood loss, angio-embolization may be appropriate. Any unstable patients should undergo rapid transfusion and emergent laparotomy for hemostasis.

Iatrogenic splenic injury during endoscopy in general is quite uncommon. However, about a dozen or more cases of splenic avulsion been reported in both patients undergoing endoscopic retrograde cholangiography or colonoscopy [78]. The mechanism is thought to be from torsional stress on the short gastric vessels or excessive tension placed on the lateral spleno-peritoneal attachments leading to capsular avulsion. Excessive bowing of the endoscope in the stomach can produce enough stress to cause similar injuries during PEG [79]. Patients with hiatal hernia and intra-thoracic stomach who undergo therapeutic upper endoscopy with insufflation may be at increased risk of undue tension on the short-gastric vessels or lateral splenic attachments [80].

Figure 15. Intrahepatic PEG placement. CT image demonstrates intra-hepatic placement in a patient who presented with acute hemodynamic instability and drop in hemoglobin 8 hours following PEG. Reproduced from Wiggins et al. with permission [77].

Retroperitoneal
Splenic / Mesenteric veins

Direct needle laceration of the splenic and superior mesenteric veins during percutaneous needle insertion has also been described as a complication of PEG, leading to fatal hemorrhage [81]. Although rare, splenic injury should be considered in patients presenting with acute hemodynamic instability and abdominal or flank pain immediately following a PEG. In a stable patient, a contrast enhanced CT of the abdomen pelvis may provide useful information. Rapid diagnosis, aggressive resuscitation, and surgical exploration with hemorrhage control can be life-saving.

CONCLUSION

Recognizing that PEG is an invasive procedure with potentially serious complications, endoscopists must be knowledgeable about the complications described here and experienced with the diagnosis and management of them. Appropriate patient selection, sound technique, use of preventative measures, and early diagnosis can minimize procedure related complications and further morbidity in a patient population already at risk.

EDITOR’S COMMENT

The endoscopist who has not experienced the complications described by Drs. Patel and Ujiki in this chapter simply has not put in enough PEGs yet. Even in the most skilled hands, PEG-related complications happen. A high clinical suspicion, early imaging and a low threshold for therapeutic intervention (whether radiologic, endoscopic, laparoscopic or open) are critical to prevent a devastating outcomes from happening after a PEG related complication. (EMP)

Chapter 140

CHRONIC COMPLICATIONS OF PEG

Faris M. Murad, MD and Jeffrey A. Blatnik, MD*
Washington University School of Medicine, St. Louis, MO, US

INTRODUCTION

Complications from placement of PEG and enteral feeding tubes can be classified as acute and chronic. Acute complications typically occur within a 2-week timeframe from the initial placement and were reviewed in Chapter 18. Chronic complications come from long-term placement of PEG (or other enteral feeding tubes) and can be broken down into major and minor complications (Table 1). Chronic complications from gastrostomy or jejunostomy tubes can be difficult to manage both endoscopically and surgically. This chapter reviews chronic complications of PEG tube placement and offers management strategies to deal with each.

Table 1. Chronic complications of PEG / PEJ Tubes

Major Complications	Minor Complications
Aspiration	Peristomal wound infections
Peritonitis	Tube obstruction or tube breaks
Gastrocutaneous fistula	Leakage around feeding tubes
Tube migration	Internal or external migration
Tube dislodgement	Granulation Tissue Formation
Hemorrhage	Mucosal Prolapse
Necrotizing fasciitis	
Tumor implantation at PEG site	
Hernia at PEG site

TUBE REPLACEMENTS

PEG tubes may require replacement either due to PEG tube dislodgement or malfunction/cracking of the PEG tube. Inadvertent PEG tube removal occurs in 1.6 to 4.4% of patients [1, 2]. Before removal or replacement of any percutaneous enteral tube, it is important to ask a few questions: 1. Is the tract thought to be mature? 2. Will the patient require continued enteral nutrition support through a percutaneous enteral tube? 3. What type of replacement tube is required? 4. Can the tube be removed without endoscopy? Of these, the most important point to keep in mind is whether there is a mature tract. The tract maturity is dependent on a variety of factors including the patient's general nutritional status and the use of immunosuppressive agents or steroids. In general, gastrostomy/jejunostomy tract maturity is complete between 2-6 weeks. It is imperative that the PEG tube is not removed before the tube tract has matured or the patient may develop a leak and peritonitis.

Prior to removing a PEG, it is critical to ensure that the patient will no longer require the tube. Such assurance would include documentation of safe swallowing capabilities, ability to meet caloric and hydration needs, resolution of obstruction (if the tube is being used for decompression), or patient/family desired withdrawal of tube (if being removed as part of a comprehensive palliative care plan; see Chapter 3). PEG tubes can be removed manually or endoscopically. Replacement tube placement (if indicated) may be performed with or without endoscopic guidance depending on the complexity of the case or other patient factors.

Figure 1. Pigtail type catheter commonly used as a gastrostomy. To remove the tube, the locking mechanism (arrow) should be released and the suture cut. As an alternative, the entire tube can be cut (inducing the suture) between the locking mechanism and the patient's skin. Unlocking and/or dividing the suture permits the Cope loop to come undone during traction withdrawal of the tube.

If a PEG tube needs to be removed due to malfunction, crack, or partial dislodgement, most can be manually removed in the office or GI lab without the use of anesthesia. It will be important to understand which type of PEG tube was placed previously (button, inflated balloon, pigtail catheter). Different types of tubes are removed in slightly different fashions. Endoscopy should be readily available in case there is a complication during manual removal (tube breaks and only a portion of the PEG is removed) although this capability does not need to be on-site of the removal location.

If the patient has a PEG tube with a pigtail, this generally requires that the PEG tube be cut to release the locking string that maintains the Cope loop (Figure 1). Once the tube is cut, the PEG tube is easily removed with manual traction. The pigtail uncurls as it passes through the PEG tube tract.

If the patient has a balloon tube to anchor the PEG, then an appropriate syringe size should be used to remove all the water within the balloon (i.e., 20 ml syringe to remove a balloon inflated with 20 ml). It is advisable to ensure that the balloon is completely empty before removing the tube, remembering that occasionally the tube may have been overinflated beyond manufacturer recommendations.

PEG tubes that were placed with an inner bolster/button require a more physical effort to remove them. The patients are typically placed in a supine position. One hand is used to secure the PEG tube and the other hand is placed over the abdomen with the thumb and index finger used to cradle the PEG tube. Constant manual traction is needed to pull on the tube while the other hands supports the abdomen and puts counter traction on the abdomen. This will result in gradual deformity and collapse of the inner bolster/button so that it can be extracted from the PEG tube tract. Such manual withdrawal can require substantial force (often novices may report that the tube is 'stuck'). The patient will experience pain as the inner bolster traverses the fascia and the skin. Often, gastric content will flow through the tract and onto the skin. Minor bleeding can be managed with pressure or silver nitrate application to the tract.

Figure 2. A) Replacement PEG tube with introducer. B) Internal PEG bumper has a dimple (arrowheads) into which the introducer is placed. C and D) Traction on the PEG against the introducer elongates and folds the bumper, allowing it to be pushed through the mature gastrostomy tract and into the stomach.

The PEG tube tract will rapidly close over the next several hours if not replaced by another tube or secured with a Foley catheter. The PEG tube tracts shrink rapidly over several hours and typically close completely in a few days. Replacement tubes typically have a balloon that is inflated once it is across the PEG tube tract and into the gastric lumen. The balloon is then inflated with the appropriate amount of sterile water to secure the gastric side of the PEG tube. Some replacement tubes have a mushroom configuration that must be straightened before passing across the PEG tube tract. Once into the stomach, the stiffening device is removed and the mushroom configuration reforms securing the tube in place (Figure 2). In both types of replacement tubes, the internal bolster/balloon prevents external migration and an external bolster might need to be applied to prevent internal migration of the tube. If there is any difficulty in placing the replacement tube, a water soluble contrast X-ray study may be useful to ensure correct placement or an endoscopy can be performed. Another option is to place a guidewire either through the PEG tube before removal or through the PEG tube tract (with or without fluoroscopy) and then replace the PEG tube over the guidewire. In the clinic setting, flushing the tube to assure easy use (the patient should experience no pain) and aspirating fluid to assess for gastric content are adjuncts to confirm placement.

TUBE CLOGS AND BREAKS

PEG tube occlusion occurs commonly for patients receiving enteral nutrition and medications through the PEG tube. The diameter of the PEG tube utilized is an important factor in patency of the tubes; the larger the diameter, the longer the patency. When the PEG tube becomes clogged, this can interrupt the patient's enteral nutrition and medications necessitating urgent intervention. Several issues must be considered with concurrent administration of medications and enteral formulas via the gastrostomy. Incorrect administration methods may result in clogged feeding tubes, decreased drug efficacy, increased adverse effects, or drug-formula incompatibilities. Liquid medications, particularly elixirs and suspensions, are preferred for enteral administration; however, these formulations may be hypertonic or contain large amounts of sorbitol, and these properties increase the potential for adverse effects. Before solid dosage forms are administered through the feeding tube, it should be determined if the medications are suitable for manipulation, such as crushing a tablet or opening a capsule. Medications should not be added directly to the enteral formula, and feeding tubes should be properly flushed with water before and after each medication is administered. Most nursing policies recommend flushing the PEG tubes with 20-30 mLs of water every 4-6 hours. This also needs to be performed before and after administration of medications and/or enteral nutrition through the PEG tube. Despite this flushing, PEG tubes still can become clogged.

Many solutions have been attempted to clear clogs including flushing water, Coca-Cola based liquids, and even pancreatic enzyme replacement therapy. One study used Creon (12,000 units lipase delayed-release capsule) dissolved in a solution of sodium bicarbonate 650 mg and sterile water. This had efficacy in clearing fewer than 50% of clogged Dobhoff feeding tubes, much less than Viokase which was taken off the market at one point [3, 4]. Another method used to clear a clogged tube is passing a tiny brush into the lumen of the PEG tube. Bard makes a manual PEG Tube Cleaning Brush (Figure 3, Bard Peripheral

Vascular, Inc. Tempe, AZ). Brushes like this can be used to help dislodge or clear a clog. One problem with some of the brushes or mechanical devices that are used to help clear a clog is that they might compress the matter within the tube and make it even more difficult to clear. Novel devices, such as flexible motor-operated brushes, offer promise as a more effective method of tube clearance (Figure 4).

PEG tubes that have broken typically need to be replaced. If the PEG tube break occurs near or within the universal/bolus adapter, then the PEG tube can be cut a few centimeters distal to the break and a replacement bolus adapter can be placed (Figure 5). This will avoid having to completely remove and replace the PEG tube. If the break is near the external bolster, then the PEG tube will need to be removed. If the break is near the external bolster, manual traction on the tube to remove it may completely break the tube leaving the internal bolster in the stomach. In this circumstance, options for management include endoscopic retrieval of the bumper or expectant observation (i.e., treat the situation as a ‘cut-and-push’ method; see below). Some patient-factors favor endoscopic retrieval, such as a known stricture of the GI tract or an individual who would be at extraordinarily high risk should the bumper result in an obstruction. If endoscopy is to be performed, a new PEG tube can be placed and its location visually confirmed.

Figure 3. Bard PEG Tube Cleaning Brush (Bard Peripheral Vascular, Inc. Tempe, AZ).

Another method of PEG removal (called the ‘cut-and-push’ method) has been described, in which the tube is cut at the skin level and the internal bumper allowed to pass through the GI tract via peristalsis. The original and follow up reports described the safety of leaving 15 Fr PEG bumpers within the gastric body [5, 6]. More recent reports have evaluated the technique in 20-24 Fr tubes as well with the authors reporting retrieval of the bumper from the stool within 48 hours in 80% of patients [7]. While larger patient series suggest the method is safe for small and large sized tubes, reports of complications (including death) have emerged when this technique is employed leading some experts to question its utility [8-11]. There are no prospective trials comparing the cut-and-push method with the traction removal method, and it logically carries some inherent risk (similar to an ingested foreign body). Unless there is a compelling reason why the tube cannot be removed by traction or endoscopically retrieved after being cut, we generally do not utilize this method.

Figure 4. Electromechanical motor-operated device that can be utilized to unclog PEG tubes (TubeClear® System, Actuated Medical, Bellefonte, PA). The system is comprised of a re-usable control box and a single use 'Clearing Stem.' One end of the Clearing Stem is attached to the control box and the other end is inserted into the feeding tube. The mechanical motion of the control box actuates the Clearing Stem Wire Brush Tip as it is advanced through the tube to actively work on and remove the clog.

Figure 5. Replacing the feeding adapter on a PEG. A) The tube clamp should be placed in the locked position to prevent leak. B) The feeding adapter is cut free of the tubing. C and D) The new feeding adapter is pushed into the tubing until the ends are flush.

BURIED BUMPER SYNDROME

One of the least described, but more common complications with long-term PEG tube use is the buried bumper syndrome (BBS). Over time, and with increased tension on the bumper, it can erode through the gastric wall and become buried somewhere below the skin. First described in the literature in 1988, the reported incidence is anywhere from 1.5-8.8% [1, 12]. In children with PEGJ tubes (PEG with jejunal extensions) the risk of developing BBS is increased, approaching 32% [13]. The etiology of BBS is related to excessive compression between the internal and external bumpers [6]. This ultimately leads to tissue ischemia and necrosis. Over time BBS can result in GI bleeding, perforation or peritonitis and abdominal wall abscess [14-16].

The typical presentation of buried bumper syndrome is tube malfunction associated with local abdominal discomfort. In general, the time to diagnosis is somewhat dependent on the functional status of the patient as those who are unable to complain about pain in the area often have a delay. In most cases, a simple history and physical exam are sufficient to diagnose a patient with BBS. A tube that does not spin on physical exam will help make the diagnosis of BBS. The addition of a CT scan or EGD can help confirm the diagnosis and is also useful for estimate the depth of bumper migration within the abdominal or gastric wall [1]. EGD will demonstrate an ulcer below the intra-gastric bumper or tissue growing over the edge of the disk (Figure 6).

Figure 6. Endoscopic view of a BBS demonstrating a partly visible internal PEG bumper with inflamed gastric mucosa overgrowing the tube.

The management of BBS depends initially on the depth of tube migration. In most cases one can simply pull the internal retention device through, often times pulling a new tube into place at the same time [17]. If there is significant tissue that has grown over the bumper, some endoscopists have described using a needle knife to expose the buried bumper [18, 19].

Caution should be taken as several authors have reported episodes of bleeding following such dissection. Local surgical interventions are reserved for those patients where the bumper has migrated into the subcutaneous tissue and requires surgical excision [20]. In those patients presenting with perforation or peritonitis laparoscopic or open abdominal exploration can facilitate removal of the bumper or control of subsequent gastric leakage or infection [21].

Prevention of BBS relies primarily on appropriate position and tension on the external bolster. When placing or evaluating a PEG tube it is imperative to ensure that the bumper is slightly loose with approximately 10 mm between the skin and the external bumper [22]. In addition it should be able to spin without difficulty. In addition it is important to frequently evaluate the PEG tube after placement to ensure that the tension on the bumper does not change as the patient may gain weight or spend additional time sitting or standing [23].

Figure 7. “Reverse” Buried bumper syndrome in a patient who presented to clinic with pain and erythema around the PEG tube. A) Before and B) after manual retrieval of the bumper.

Another related entity that is poorly described in the literature is ‘reverse’ BBS. Here, the external bumper of the PEG tube erodes through the skin and into the subcutaneous tissue while the internal bumper remains in a functional, intra-gastric position. Patients generally present with pain and erythema around the tube and physical exam reveals absence of the external bumper of the PEG tube (Figure 7). If possible, the bumper can be retrieved in the clinic or operating room (if necessary) and reset to have significantly less tension.

PERISTOMAL LEAKAGE AND SKIN IRRITATION

The reported incidence of peristomal leakage is 1-2% [24]. There are multiple factors that must be considered when evaluating a patient with peristomal leakage (Table 2). A small amount of mucoid discharge from the tract is normal. Similarly, mild oozing of fluid around the PEG tube is normal in the short term after placement. This typically goes away after a few weeks. If there is persistent output of fluid, then it must be determined if this is due to an infection or persistent leak. A persistent leak may occur due to the skin incision being too large at time of placement. It is important that during placement, the skin incision is kept to a minimum. This will allow the subcutaneous tissue to be closely approximated to the PEG tube.

Table 2. Potential causes of gastrostomy tube leak

Potential Causes of Leak Around a PEG Tube	
1.	Tube displacement
2.	Recent weight loss
3.	Inadequate tube stabilization (internal/external bumpers loose)
4.	Failure of tract closure/approximation around tube (inadequate wound healing)
5.	Too large an incision at time of PEG tube placement
6.	Increased intraabdominal or intragastric pressure:
a.	Cough, constipation, straining
b.	Inability to decompress gastric contents (high residual volumes)
c.	Delayed gastric motility

The first thing to determine with persistent leaking of a PEG tube is whether the tube is in the correct place. If the tube is correctly positioned the tension on the bumpers should be checked (to ensure that it is neither too loose nor too tight). Balloon gastrostomy should be checked for appropriate balloon inflation. The PEG tube and skin site should be kept clean and dry by washing it with soap and water. Excessive tension of the external bolster should be avoided to prevent the complication of skin ulceration and development of buried bumper syndrome.

Treatment should begin with optimizing the patient's nutritional status and glycemic control. Barrier creams and other types of skin protectants with zinc oxide may reduce the irritation around the skin being exposed to leaking gastric contents. Using acid suppression such as proton pump inhibitors or Histamine 2-blockers may also help reduce irritation by raising the pH of the leaking fluid. Other principles of managing leakage around tubes is to minimize tension and movement. Conversion of PEG tubes to low profile tube (button) may help in minimizing movement of the tube, as can tube stabilizing devices.

If leaking persists and there are associated complications, this can be managed in several ways. The tube can be upsized to see if this helps reduce the amount of leakage around the tube. Upsizing the tube should not be the first step in managing a leak as it can potentially worsen the situation if the original reason for leak (for example tube motion) was not addressed. In such circumstances the larger tube will eventually leak as well and the resultant PEG tract will now be even larger. Another option would be to remove the PEG tube altogether for several days to allow the PEG tube tract to partially close. The tract will need to be secured with something smaller (guidewire or smaller catheter) so that a new PEG tube can then be placed in the same site [25].

PERSISTENT GASTROGASTROSTOMY FISTULA

PEG tubes that have been in place for an extended time (> 6 months) develop a mature tract. Typically after the PEG tube is removed, the PEG tube tract closes on its own. Persistent gastrocutaneous (GC) fistulae are rare and account for approximately 0.5-3.9% of patients who have had long term PEG tubes. Several factors (mentioned earlier) hamper healing and closure of the PEG tube tract. The crucial element thought to influence

persistence of a chronic GC fistula is epithelialization of the PEG tube tract. Such fistulae can be problematic for patients due to persistent skin irritation, superimposed bacterial and fungal infections as well as issues with cleanliness and soilage of dressings and clothes (Figure 8).

Conservative management includes dietary modification (avoiding oral liquids without solid food to thicken gastric contents), topical therapy to protect the skin and treat any infections and local therapy with silver nitrate to chemically cauterize the epithelial tract. The majority of fistulae can be managed in this fashion. Fistulae failing conservative therapy can be managed endoscopically. See Chapter 20 for a complete discussion of endoscopic management of persistent GC fistulae. Fistulae failing both conservative and endoscopic management should be considered for laparoscopic or open surgical takedown.

Figure 8. Persistent GC fistula 1.5 years after PEG removal in a patient who underwent surgery for a head and neck malignancy. Patient wore an ostomy appliance to collect gastric effluent and had a superimposed area of fungal infection that responded to topical therapy. His fistula was closed endoscopically.

PEG SITE HERNIA

The occurrence of a hernia at the PEG site is a rare, but documented complication (Figure 9). The literature on hernia following PEG tube removal is limited primarily to case reports. Bolbo-Roda et al. described a 43 year old male who underwent PEG tube placement for oral malignancy [26]. Following removal the patient presented with gastric leak and 4 months following tube removal the patient returned with an abdominal wall defect in the area of his previous PEG tube. Kaplan and Delegge described a 66 year old female who underwent a 24 Fr PEG tube placement for squamous cell carcinoma of the vocal cords [27]. In the initial period following tube placement she had some issues with local superficial cellulitis. The tube was eventually removed after 7 months of use and the patient returned to the clinic 2 months later with complaint of a bulge at the former PEG site. CT scan on the patient demonstrated a Richter's style hernia. McElrath et al. described the even more rare combination of a persistent GC fistula and a PEG site hernia in a 69 year old male who ultimately required a laparoscopic fistula takedown and herniorrhaphy 4 months following PEG removal [28].

One reason for the relatively rare presentation of a hernia at a former PEG site is the survival of most PEG patients is typically limited by their underlying illness that necessitated the PEG tube in the first place. In general, patients do not survive long-enough to form a hernia or never have their tube removed. The same considerations for tube placement should be reevaluated when deciding if surgical repair of the hernia is necessary. If the patients expected survival is limited, and the hernia is asymptomatic, then a non-operative approach to repair can be undertaken. Risk factors for hernia formation likely follow the same as those for any incisional hernia; midline placement, obesity, history of wound infection, larger diameter PEG tube.

Figure 9. PEG site hernias. A) PEG site hernia from midline placement of a PEG in a patient with preexisting diastasis of the rectus muscles. B) Laparoscopic view of a PEG site hernia with the old gastrostomy site (arrow) present in the hernia.

GRANULOMA FORMATION

Hypergranulation tissue formation is a common complication of PEG placement with reported occurrences above 50% [29]. Risk factors include trauma, friction, ill-fitting low profile tube, and moisture [30]. Many treatments for granulation tissue exist. First, a clinician must identify and treat any possible infection, minimizing external irritation, prevent excessive moisture. Topical application of 0.5% triamcinolone application or polyurethane foam has been described [31]. In addition, many clinicians use silver nitrate or cryotherapy on the tissue. Surgical excision of the tissue can also be performed [32]. All of these treatments are equally efficacious with none being reported to be superior to the other [30].

MANAGEMENT OF PEG DURING SUBSEQUENT PROCEDURES

Management of previously placed PEG tube at the time of an additional procedure depends primarily on the type of procedure to be performed and the location of any necessary incision. For patients who are undergoing a procedure that does not require an abdominal incision, the PEG tube can simply be secured to the abdomen to minimize accidental dislodgement. In those patients who require an abdominal wall incision, the PEG tube should

be prepped out of the field when possible, or excluded by using a sterile drape after the abdomen is prepped. If the tube itself is in a location interfering with the procedure, it can be removed before and replaced at the conclusion of the procedure. For patients undergoing upper endoscopy, it is crucial to ensure that the PEG tube is appropriately capped when insufflating the stomach as this can lead to difficulty with appropriate visualization, as well as spillage of gastric contents through the PEG tube itself.

CONCLUSION

Long term complications of PEG tube are well described, and most can be successfully managed while maintaining a functioning tube. Occasionally, such problems cannot be managed conservatively and endoscopic or surgical therapy may be indicated, including removal and replacement of the PEG.

EDITOR'S COMMENT

This chapter describes many of the commonly identified chronic complications associated with PEG tube placement. Most of these issues are not life threatening but can dramatically alter quality of life. Understanding how to manage these postoperative problems is as vital as the comprehension of safe PEG tube placement. (JMM)

Chapter 141

ENDOSCOPIC MANAGEMENT OF PEG RELATED COMPLICATIONS

Joshua S. Winder, MD and Eric M. Pauli*, MD

Penn State Hershey Medical Center, Hershey, PA, US

INTRODUCTION

As outlined in the previous two chapters, PEG tube placement has a set of well-defined risks and potential complications. Familiarity with proper technique and relevant anatomy is key to minimizing the risk of undesired outcomes. However, even with technical expertise and appropriate peri-procedural management, complications may still occur. In this chapter we will examine endoscopic management of a variety of adverse events following PEG placement. It should be emphasized that any patient presenting with hemodynamic instability, sepsis, or peritonitis as a result of any of a PEG complication is not a candidate for endoscopic therapy and should be managed by a traditional surgical approach.

ACUTE GI BLEEDING

PEG placement is considered a higher risk procedure with an overall bleeding complication rate of 2.5% [1]. Management of bleeding is dictated by the nature and severity of the hemorrhage. Most bleeding from the abdominal wall puncture site can be controlled with direct pressure. Should the patient present with frank blood aspirated from the PEG tube, hematemesis, hematochezia, melena, drop in hemoglobin (acute blood loss anemia), or hemodynamic instability, an upper endoscopy should be performed to assess and potentially treat the source (Figure 1). Often in these cases, bleeding can be seen from the gastrostomy tract, or from gastric ulceration (often occurring in the setting where the PEG bumper is pulled too tightly against the gastric mucosa). Local endoscopic management of the hemorrhage can be achieved with traditional endoscopic techniques including electrocautery,

* Corresponding Author's Email: epauli@hmc.psu.edu.

clipping, and injection therapy. While a recent meta-analysis concluded that endoscopic clipping was superior to injection alone (but comparable to thermocoagulation) in the setting of non-variceal upper gastrointestinal (GI) hemorrhage, we prefer to utilize multimodal therapy to manage this problem [2]. Additional consideration should be given to the possibility that traditional endoclips may be dislodged by the motion of the internal PEG bumper against the clip itself, which can lead to re-bleeding.

COLON INJURIES

Perforation of the transverse or sigmoid colon may occur when the colon is located between the abdominal wall and the anterior wall of the stomach. Although techniques such as using a pilot needle or utilizing the safe-tract were developed to prevent such perforations, this injury continues to occur. Patients may be completely asymptomatic or present with abdominal pain, diarrhea (from the administration of tube feeds to the colon), tenderness, peritonitis, or sepsis. Patients who present in extremis merit a formal operation with repair of the perforation (or perforations, as the anterior and posterior wall of the colon are typically both involved) while simultaneously establishing enteral feeding access.

Misplacement of a PEG through the colon is often an unrecognized event. Even with a through-and-through colon injury, the endoscopic view of stomach will show the PEG bumper in what appears to be a proper position. Utilizing a finder needle may not be sufficient if the same tract is not followed with the angiocatheter needle or trocar. When aspirating with a small gauge finder needle, there may be insufficient air in the colon or the enteric content may be too thick to pass into the syringe with aspiration to signal the endoscopist that colonic puncture has occurred.

Trans-colonic PEG placement results in both gastrocolic and colocutaneous fistulae. In asymptomatic patients or those with vague abdominal complaints, the injury may be identified on routine colonoscopy.

Figure 1. Post-PEG bleeding due to ulceration of the gastric mucosa at the PEG tube site from excessive traction. A) Endoscopic evaluation demonstrated blood in the body of the stomach and no active bleeding from the gastrostomy. B) Blood clot was found in the pre-pyloric region.

Figure 2. Colon injury after PEG placement; Plain abdominal film following contrast injection via gastrostomy demonstrates contrast outlining the haustral folds of the splenic flexure and descending colon.

Other patients may not have the injury identified until months later when the PEG tube bumper migrates into the colon or is positioned intra-colonic during PEG tube replacement [3]. Such patients may present with copious diarrhea immediately after initiation of tube feeds, but may otherwise be stable. Diagnosis is made by injecting contrast through the PEG tube and identifying haustral folds outlined by contrast on plain x-ray, or identifying the bumper and injected contrast within the lumen of the colon on computed tomography (Figure 2).

Conservative management includes removing the PEG at the bedside and allowing spontaneous closure of the fistulae [3]. A localized abscess or generalized peritonitis may develop depending on the age of the tract and whether or not a fully epithelialized fistula has developed. A small percentage of these fistulae persist which may not be acceptable based on the patients' comorbid conditions, life expectancy, and preference.

Endoscopic management has the potential to simultaneously address the three problems created by this scenario: repair of the gastrocolic fistula, repair of the colocutaneous fistula, and reestablishment of enteral feeding access. Prior to intervention and once intra-colonic location has been verified by imaging, colon prep can be administered through the PEG tube to facilitate colonoscopy. Our preference has been to first address the gastrocolic fistula [4]. During upper endoscopy the fistula can be readily identified on the anterior wall of the stomach (Figure 3A). We advocate for superficial ablation of the tract with an argon plasma coagulation catheter to disrupt the epithelialized superficial layer and induce inflammation that will further obliterate the tract [5]. An over-the-scope clip (OTSC) or other endoscopic closure device can then be placed at the opening of the tract (Figure 3B). We routinely verify closure fluoroscopically by instilling contrast within the lumen at the location of clip placement.

Figure 3. A) Endoscopic view of a gastrocolic fistula on the anterior wall of the stomach. B) Closure of fistula utilizing an OTSC.

Figure 4. Colonoscopic view of a gastrostomy bumper within the transverse colon resulting from a transcolonic PEG tube placement.

With the gastrocolic fistula closed, a colonoscopy is then performed to identify the location of the colocutaneous fistula. The PEG bumper should be easily visualized within the lumen of the colon (Figure 4). We prefer to utilize a ‘cut and push’ method of tube removal rather than a simple removal under traction to prevent any further dilation/enlargement of the colocutaneous fistula tract. The PEG is cut close to the level of the skin and a flexible guidewire is passed through the cut lumen of the PEG. Using a Roth net the PEG bumper and flexible wire are secured endoscopically and removed per rectum. This results in a flexible guidewire that traverses the colocutaneous fistula, travels distally through the colon, and traverses the anus. Backloading this guidewire through the working channel of the colonoscope serves two main purposes: it facilitates identification of the fistula in what may be a difficult location such as the splenic flexure, and assists in OTSC placement by allowing the colonoscope to be pulled into position (i.e., pull colonoscopy) by applying gentle traction on the externalized wire at the fistula site. A Foley catheter can be placed into the tract to enable insufflation during the remainder of the colonoscopy. Alternatively, petroleum impregnated gauze can be placed over the cutaneous opening to eliminate air leak. Once the colonoscope has reached the fistula, the Foley is deflated and removed and an OTSC (or other

endoscopic closure device) is applied and closure verified fluoroscopically. The wire can then be removed.

If the patient's underlying condition requires continued enteral feeding access, it can be addressed at this time. The new PEG tube is placed following traditional techniques described in earlier chapters, but with the following modifications: In order to find an appropriate tract that will not traverse the colon once again, fluoroscopy is used with intra-colonic contrast, in addition to transillumination, external depression of the abdominal wall, and a safe-tract technique. Additionally, once the guidewire has been passed into the stomach, colonoscopic visualization should be utilized to ensure that the wire does not traverse the colon. Colonoscopic maneuvers may be required to obtain a safe window (decompressing the colon, rotating the transverse colon, etc.), which may be facilitated by the presence of an additional endoscopist [4, 6].

GASTROSTOMY SITE LEAK

The incidence of leak around the PEG tube has been reported at 1-4% though this number is likely much higher due to underreporting [7, 8]. Risk factors contributing to leakage including diabetes, malnutrition, immunosuppression, infection, gastric hypersecretion, side torsion on the PEG tube, excessive cleansing of the site, absence of an external bolster, or if the bolster is too tight. Modification of these factors should be attempted whenever possible.

There are a number of endoscopic techniques that can slow and even stop leakage. The aperture of the gastrostomy can be decreased by applying an OTSC on the luminal surface at the edge of the PEG tube (Figure 5). Plication can also be performed with endoscopic suturing or a combination of suturing and clips (Figure 6). Alternatively, a detachable ligating device can be placed around the PEG tube and sequentially secured to the mucosa with endoclips. Once the ligation loop is tightened, the result is a cinching of the gastric mucosa around the PEG similar to a purse string suture (Figure 7).

Figure 5. Over-the-scope clip applied adjacent to an existing PEG tube to close the aperture around the leaking PEG.

Figure 6. Endoscopic suturing device being used to plicate the adjacent mucosa surrounding the PEG tube in the setting of a leaking PEG.

Figure 7. A) Detachable ligating device placed around PEG tube with endoclips placed sequentially around PEG securing the loop to the gastric mucosa. B) Closure of the ligation loop creates a cinch of gastric mucosa around the PEG resulting in smaller aperture of the gastrostomy similar to purse string suture.

If leakage persists or is exacerbated when tube feeds are given, conversion to a gastrojejunal tube should be considered. Advantages of this approach include continued enteral access via the jejunal extension, post-pyloric feeds which should decrease the total amount of gastric contents and subsequently reduce the amount of leakage, and persistent access to the stomach through the gastric port which can be used both for infusion and drainage (venting). In the patient with a well-established gastrostomy tract, the PEG tube can be removed and a flexible wire placed through the gastrostomy. The wire can then be endoscopically directed through the pylorus and past the ligament of Treitz. The gastrojejunostomy tube can then be placed over the wire. Final position can then be assessed using fluoroscopy and injection of contrast through the jejunostomy tube. Some PEG tube brands allow placement of a jejunostomy extension through the existing PEG tube. In these cases the jejunostomy extension can be dragged into position endoscopically. See Chapter 11 for a more detailed description of the technical steps of placing a gastrojejunal tube.

Figure 8. Laparoscopic view of a 7 day-old PEG tube in a severely malnourished patient presenting with intraperitoneal leakage of tube feeds. The anterior wall of the stomach has yet to fuse with the anterior abdominal wall and there is no omentum surrounding the gastrotomy site.

Figure 9. Gastrointestinal T-anchors (arrows) placed in triangle pattern around a leaking PEG tube to afford gastropexy.

Gastrointestinal T-anchors can be used in cases where leakage is occurring around the tube and into the peritoneal cavity. In these patients the serosa of the anterior stomach has not become adherent to the peritoneum of the anterior abdominal wall (Figure 8). Ideally 3-4 anchors (forming either a triangle or a square) would be placed sequentially around the existing PEG tube to pexy the stomach to the anterior abdominal wall (Figure 9). Care should be taken when placing T-anchors around a balloon-type gastrostomy as the introducer needle can easily rupture the balloon, necessitating tube exchange.

PERSISTENT GASTROGASTROUS FISTULA

Gastrocutaneous (GC) fistulae occur when PEG tubes are removed and a persistent tract results. While the overwhelming majority of these fistulae close spontaneously, approximately 1.1% persist and require further treatment [9]. Traditional therapies include application of silver nitrate to the external opening, limiting oral intake and providing post-

pyloric feeding access such as nasojejunal feeds, or in some cases laparoscopic or open fistula takedown.

Our experience with endoscopic closure of persistent GC fistula closure with OTSC's has been positive with a long-term success rate of 100% in 5 cases (Figure 10) [5]. Fistulae up to 2 cm in diameter have been successfully closed using OTSC's [10]. Alternatively, endoscopic suturing devices can be used for GC fistulae, including those larger than 2 cm [11].

Fistula formation and persistence are multifactorial and must be addressed as such in order to achieve long-term closure. We advocate removal of any foreign material that may be present in the tract (typically suture material), treatment of any associated infection (adjacent abscess or overlying cellulitis) with drainage and/or appropriate antibiotics, optimization of nutrition with enteral feeding whenever possible (which may require alternate access such as nasojejunal feeds as mentioned previously), optimization of medical comorbidities including diabetes, cessation or tapering of steroids if possible, relieving downstream obstructions or strictures (including pyloric injection with botulinum toxin in select cases), and ablation of the epithelialized tract with argon plasma coagulation or mechanical debridement [12].

EARLY PEG-TUBE DISLODGMT

Inadvertent removal of the PEG tube is a relatively uncommon, but well-known occurrence. Previous authors have reported a dislodgment rate of 2-28% [13, 14]. Dislodgment in the patient with a well-established gastrostomy tract becomes a minor issue and can be replaced at the bedside with a new gastrostomy tube, verifying intra-gastric positioning with contrast injection through the newly placed tube as indicated. However, in patients where the gastric serosa has not yet fused to the peritoneum of the abdominal wall and the tract has not yet fully matured (1-2 weeks) a dislodged PEG tube may result in a free spillage of gastric contents into the abdominal cavity [15]. The period from placement to tract maturation can vary based on the patient's baseline comorbidities and nutritional status, further prolonging tract-maturation time. The patient's presentation will dictate the management; patients displaying signs of peritonitis, sepsis, or hemodynamic instability require emergent operative intervention with abdominal washout, closure of the previous gastrostomy, and creation of a new gastrostomy at a separate site.

Figure 10. Abdominal wall of a patient with a persistent gastrocutaneous fistula following PEG removal. A) Before and B) Three weeks after closure with an over-the-scope clip.

Figure 11. Endoscopic snare awaiting passage of a guidewire through a recently removed gastrostomy tract. Newly placed T-anchor is visible lateral to the former PEG tube site.

In the stable patient there are various management options. Historically, the gastrostomy tube could be blindly placed through the immature tract. Water-soluble contrast was then injected to verify placement. Misplacement could result in dire consequences with the patient developing peritonitis from a misplaced gastrostomy tube. Conservative management was also acceptable, consisting of nasogastric tube decompression and antibiotics with repeated PEG tube placement 7-10 days afterwards [16].

There are a number of endoscopic options for early PEG tube dislodgment in the stable patient. The first is semi-urgent upper endoscopy, percutaneous insertion of a flexible wire or silk suture under direct endoscopic visualization, and then replacement of the PEG tube through the original gastrostomy. Galat and colleagues used this technique in 5 consecutive patients with PEG dislodgement with good results [13]. Another option is to place a new PEG tube at an alternate site, pulling the anterior wall of the stomach to the abdominal wall and occluding the previous gastrostomy. The endoscopist can additionally use T-anchors to achieve a more definitive gastropexy, especially in patients at risk for repeated PEG tube dislodgements (Figure 11). Alternatively, the previous gastrostomy can be closed using OTSC's as described previously and a new PEG placed at an alternate site.

PEG Rescue

Marks et al. first described rescue of a dislodged PEG using a method based on natural orifice transluminal endoscopic surgery (NOTES) principles [17]. The technique, a so-called PEG Rescue, proceeds as follows: an upper endoscopy utilizing carbon dioxide insufflation is performed and the gastrostomy identified (Figure 12A). If it is patent, the gastrostomy is dilated pneumatically with balloon dilation to allow passage of the endoscope into the peritoneal cavity (Figure 12B). A systematic examination of the abdominal cavity is then performed to inspect the abdominal viscera for injury or compromise. Any identified abscess, succus, or free fluid can be aspirated at this point. The abdominal wall defect can be used to pass a 5 mm laparoscopic suction/irrigation device to aid in peritoneal lavage, with the trans-gastric endoscope being used for visualization.

Figure 12. PEG Rescue technique. A) Endoscopic view of a gastrotomy following early PEG dislodgement. B) Balloon dilation of the gastrotomy utilizing a 10 mm radially expanding balloon. C) Endoscopic view of the liver and falciform ligament. A transabdominal guidewire is being passed through a snare. D) The guidewire withdrawn into the stomach and is ultimately retrieved per os to permit a new PEG tube to be placed.

After a determination has been made that no formal surgical intervention is necessary, the PEG guidewire is then passed through the abdominal wall defect and grasped with a snare (Figure 11C). The guidewire is then pulled back to an intra-gastric position and ultimately retrieved per os (Figure 11D). The remainder of the procedure proceeds similar to a standard pull-method PEG placement. As the gastrostomy tube is pulled into position, the anterior wall of the stomach is drawn up against the anterior abdominal wall as it was prior to dislodgement. Gastrointestinal T-anchors should be placed to further secure the gastrostomy. Tube feeds can be restarted once the patient is clinically stable, at the provider's discretion. We have performed PEG rescue in multiple cases of stable patients and the results have been very positive.

CONCLUSION

Endoscopic therapies are appropriate in many settings where PEG tube related complications have occurred. The guiding principle for endoscopic management is the clinical stability of the patient. In the stable patient, we recommend all of the above interventions when appropriate with the understanding that endoscopic therapies should only be offered by those who are experienced in their respective applications.

EDITOR'S COMMENT

This chapter gives a comprehensive description of the many complications associated with PEG placement and the associated management options. The majority of these issues revolve around troublesome post-procedure scenarios such as PEG site leakage or gastrostomy site enlargement. Life threatening complications can also develop and endoscopists must be aware of these and the appropriate evaluation and management techniques (JMM).

Chapter 142

GASTRIC BYPASS SURGERY AND THE SKIN

Katherine Fiala, MD and Ryan Batson

Scott and White Hospital, Texas A&M Health Science Center College of Medicine,
Temple, TX, US

ABSTRACT

Gastric bypass surgery can affect the skin in both positive and negative ways. Recently, the positive outcomes have been demonstrated with psoriasis, necrobiosis lipoidica, acanthosis nigricans, and hidradenitis suppurativa. In this chapter, we will discuss the recent findings of the relationship between gastric bypass and these four skin disorders. On the other hand, with aims to achieve radical weight reduction, bariatric surgery can be accompanied by nutrient insufficiencies and metabolic imbalances that affect the skin. Such deficiencies can lead to changes in the skin's micro-architecture which can, in turn, affect processes such as wound healing. Changes in the skin's immunity and defense mechanisms can result from vitamin and nutrient deficiency. The nutrient deficiencies are thought to be a result of a combination of decreased food intake, changes in the digestive system's anatomy, and high levels of oxidative stress that interfere with the absorptive process. This chapter will explore the most prominent metabolic and nutritional deficiencies that have dermatologic manifestations including: iron, biotin, zinc, copper, and vitamins B3, A, C, and K. Interestingly, patients may be compliant with their oral nutritional supplements, but the absorption is decreased resulting in low circulating levels. This can, moreover, result in skin and systemic manifestations. Recognizing various skin changes secondary to nutrient deficiency in post bariatric surgery patients is a valuable asset in providing comprehensive care.

BENEFITS TO THE SKIN

Psoriasis

Psoriasis is a common chronic inflammatory condition characterized by high epithelial cell turnover. The classic cutaneous manifestation includes red patches with overlying thick, silvery scales, which may be itchy. The distribution is often symmetrical and shows

predilection for the elbows, knees, scalp, and nails (Farias, 2012). Obesity is noted to be a major risk factor for psoriasis. Perhaps one of the greatest contributions to the increased incidence of psoriasis in the obese patient population is the chronic inflammatory state imposed on the body. Psoriasis is regarded as a systemic autoimmune disease in which leukocytes, inflammatory cytokines, and dendritic cells play a role (Faurischou 2011). Pro-inflammatory cytokines such as tumor necrosis factor (TNF) alpha, interleukin (IL)-1, IL-6, IL-8 and leptin synthesized by adipose tissue are over expressed in obesity (Hector, 2014). Furthermore, the severity of psoriasis is associated with the degree of obesity observed. Hossler et al. noted that almost two-thirds of their 24 patients with psoriasis self-reported postoperative improvement after undergoing weight loss surgery. In addition, this study demonstrated an improved response to psoriasis treatment after surgery (Hossler 2013).

Interestingly, while it is no surprise that drastic weight loss after the surgery reduces symptoms of psoriasis, marked clinical improvement may be noted immediately following the procedure even before significant weight loss is achieved. The suspected mechanism involves the glucose lowering gut incretin hormone, glucagon-like peptide-1 (GLP-1). After gastric bypass, the levels of postprandial GLP-1 may increase up to 20 fold (Faurischou 2011). This hormone is not, however, increased in the purely restrictive surgeries, including gastric band or sleeve. GLP-1 is found in the epithelium of the intestinal tract with the greatest density located in the ileum. It is secreted in response to the presence of nutrients in the intestinal lumen (Holst 2007). The GLP-1 receptors on pancreatic beta cells have been shown to enhance all steps of insulin biosynthesis and insulin gene transcription as well as beta cell mass (in cell and animal studies). GLP-1 also inhibits the secretion of glucagon from alpha cells. It is the cumulative effects on insulin and glucagon that ultimately inhibit hepatic glucose production (Faurischou 2011). Lastly, GLP-1 reduces appetite, gastrointestinal motility, and emptying. These effects ultimately lead to decreased food intake.

In addition to contributing to glucose homeostasis, gut motility, and satiety, GLP-1 has been shown to have some anti-inflammatory effects. It is this implication as an immunological modulator that provides an additional contribution to the improvement of psoriasis postoperatively (Faurischou 2011). Its anti-inflammatory actions include decreased expression of cytokines induced by TNF-alpha. This is of special interest when understanding the mechanism of psoriasis resolution. TNF-alpha promotes inflammation through the pro-survival transcription factor NF-kB (Pasparakis 2009). Although data on immunological effects of GLP-1 are still primarily based on *in vitro* and animal models, new and exciting data are emerging. The potential immunological effects pose a link between bariatric surgery, GLP-1 and psoriasis.

Ultimately, it is the additive effects of improved glucose homeostasis, increased weight loss, and reduced inflammation that result in improved psoriasis. Farias et al. reported that seven of the 10 patients in their study remained in remission six months after surgery. Seventy-five percent of these patients were previously taking systemic medications including: acitretin, methotrexate, and cyclosporine. By achieving resolution of psoriasis with a bariatric procedure, serious side effects of these systemic medications may be avoided (Farias 2012). Despite the fact that psoriasis is not considered a life-threatening illness, it is associated with stigmatizing chronic lesions that affect a patient's physical and psychological morbidity. Gastric bypass, therefore, may provide an effective means of treating patients with refractory psoriasis and, ultimately, significantly contribute to an improved quality of life.

Necrobiosis Lipoidica

Necrobiosis lipoidica (NL), a granulomatous skin disease, is commonly associated with diabetes mellitus. It is typically observed bilaterally on patients' shins, but may also be seen on the forearms, hands and trunk. In the initial stages, the lesions are typically asymptomatic but may become tender and ulcerate over time or when injured. The initial presenting symptom is the appearance of an "erythematous ecchymosis." The lesions are red-brown and indurated with smooth, atrophic central portions. Over time, the chronic disease may lead to ulceration which can then cause dysesthesia, pain, secondary infection and cosmetically sensitive scarring (Weismann 2004).

While the etiology of NL is still largely unknown, some of the proposed mechanisms implicated include: T cell involvement, microangiopathy, and immune complex vasculitis resulting in a release of pro-inflammatory cytokines and abnormal collagen production (Sehgal 2011).

The diagnosis is made by punch biopsy demonstrating superficial and deep perivascular and interstitial mixed inflammatory cell infiltrates including: lymphocytes, plasma cells, multinucleated histiocytes, and eosinophils in the dermis and subcutis. Necrotic areas with collagen degeneration in the deep dermis, peripheral fibrosis, and subcutaneous tissue panniculitis may also be diagnostic (Patsatsi 2011).

A very poor response to treatments, including topical and systemic steroids, nicotinamide, pentoxifylline, tretinoin, TNF alpha inhibitors, mycophenolate mofetil, thalidomide, cyclosporine, tacrolimus, and antimalarials, is typically observed in most patients with this condition (Bozkurt 2013; Patsatsi, 2011). Case reports, however, have detected symptomatic, morphologic, and histopathologic remission of NL after bariatric surgery (Bozkurt 2013). It is believed that the significant improvement of a patient's NL is secondary to type 2 diabetes mellitus remission (Bozkurt 2013). This provides a promising therapeutic option for morbidly obese patients with NL who failed medical therapy.

Acanthosis Nigricans

Acanthosis nigricans is a common dermatologic manifestation of obesity, insulin resistance, and consequent hyperinsulinemia. It is classically a symmetrical hyperpigmented, velvety plaque that may occur in almost any location. The most common regions affected include the posterior neck, axilla, and groin. Additionally, less common regions include the knuckles, elbows, and face (Atwa 2014). The skin has abundant insulin-like growth factor-1 (IGF-1) receptors on the keratinocyte surface membrane. Acanthosis nigricans is a common feature in severe insulin resistance, in patients with insulin receptor disorders, and hyperinsulinemia (Babieri 1983; Pugeat 2000; Cruz 1992; Stuart 1986). Large amounts of unbound insulin are free to bind IGF-1 receptors on keratinocytes or fibroblasts, leading to proliferation of the epidermis (Barbieri 1983). Reduced fasting insulin and C-peptide levels suggest that daily insulin levels status post gastric bypass surgery are likely secondary to reduced free fatty acids, leptin, or gut incretins. Moreover, the dramatic decrease of circulating leptin occurring after gastric bypass may contribute to reduced acanthosis nigricans and hyperandrogenism. Androgens target the skin and lead to hair growth and sebum secretion. Increased secretion of testosterone, the main active androgen, can lead to

dermatologic manifestations including hirsutism, acne, alopecia, and acanthosis nigricans. A decrease in androgens by the aforementioned mechanism, in addition to decreased active androgen synthesis in human adipose tissue, leads to improvement of acanthosis nigricans. In summary, the combined effects of decreased insulin resistance in addition to reduced levels of systemic androgens results in the improvement of acanthosis nigricans.

Hidradenitis Suppurativa

Hidradenitis suppurativa (HS) and acne inversa are chronic relapsing, scarring skin conditions involving the follicular and pilosebaceous units, which have a damaging impact on patients' quality of life. Diagnostic criteria for HS is clinical and must meet the following three criteria: typical lesions (deep-seated painful nodules, abscesses, draining sinuses, bridged scars, and open comedones within secondary lesions); typical topography in one or more of the predilected areas (intertrigionous skin of the axillary, inguinal, genital, perineal, or infra-mammary regions); and chronicity and recurrence (Revuz 2016; Margesson 2014). The myriad of complications that may result include anal and perianal fistulae, arthropathy, lymphedema, and, even, squamous cell carcinoma of the buttocks and perineum.

Lack of early detection, accurate diagnosis, and proper therapy resulting in relapsing and severe HS is a common occurrence. The influence of endogenous reproductive hormones, exogenous hormones and androgens lead to keratin plugging and distention of the follicular unit. Shearing forces, friction, and pressure ultimately lead to rupture and leakage of the ductal contents, resulting in an inflammatory reaction that is mediated by the innate immune system (Margesson 2014). Given this pathophysiology, the chronic state of inflammation observed in obesity makes it an obvious risk factor for this condition. Additionally, in obesity, the hyperandrogenism, elevated insulin, and elevated IGF-1 activate androgen receptors that control growth. As a result, there is uncontrolled cellular proliferation and subsequent follicular duct plugging. The role of obesity in the pathophysiology of HS was further supported by Thomas et al. in a case report of a man who experienced rapid improvement of long-standing, treatment-resistant HS after bariatric surgical intervention (gastric sleeve) and subsequent drastic weight loss. The improvement was noted within weeks of the surgical intervention, and the patient remained in remission for over a year following the procedure (Thomas 2014). This highlights the rationale that weight loss plays an important role in the intervention of HS and, ultimately, the prevention of the more severe complications that may follow. Standard therapy includes lifestyle modifications such as dietary compliance and weight loss, avoidance of trauma that leads to follicular rupture and active multimodal anti-inflammatory therapy. Given the importance of weight loss in the aims to resolve HS, bariatric intervention (both restrictive and malabsorptive) may be viewed as a means to achieve the drastic reduction in weight needed in patients who struggle to accomplish this without surgical intervention.

RISKS TO THE SKIN

While the aforementioned are examples of the positive effects of gastric bypass surgery on the skin, achieving radical weight reduction via an invasive bariatric procedure is not

without inherent risks and complications. Bariatric surgery includes restrictive procedures such as laparoscopic banding, sleeves, and malabsorptive procedures including Roux-en-Y-gastric bypass (RYGB) and biliopancreatic diversion. The most common method is RYGB where an isolated portion of the stomach is directly connected to the small intestine, resulting in decreased gastric capacity, decreased acid secretion and diminished nutrient absorption. Bariatric surgery can be accompanied by micronutrient insufficiencies and metabolic imbalances that affect the skin. Such deficiencies can lead to changes in the skin's micro-architecture, which can, in turn, affect processes including wound healing. Changes in the skin's immune defense mechanisms can also result from vitamin and nutrient deficiency, increasing susceptibility to pathogens (Zouridaki 2014). The nutrient insufficiencies are presumed to be a result of a combination of decreased food intake, changes in the digestive system's anatomy, and high levels of oxidative stress that interfere with the absorptive process (Halawi 2013). The specific nutrition-related complications that will be detailed in this chapter include vitamin A, vitamin B3, biotin, vitamin C, iron, copper, vitamin K, and zinc. In attempt to prevent the dermatologic complications, post-bariatric patients are routinely prescribed dietary supplements to compensate for future insufficiencies. Interestingly, while patients may be compliant with their oral nutritional supplements, low circulating levels can still persist since the absorption is decreased. Recognizing various skin changes secondary to nutrient deficiency in post bariatric surgery patients is a valuable asset in providing comprehensive care.

Vitamin A

Vitamin A or retinol is a liposoluble vitamin found in foods derived from sources including cow's milk, liver, eggs, fish oils, mangos, tomatoes, and beta-carotene containing vegetables. Vitamin A is vital for optimum immune system function (Zalesin 2011; Jen 2010). Deficiency in retinol may be due to inadequate intake in patients with restricted diets or various metabolic alterations observed after gastric bypass procedures. These alterations include fat malabsorption, diminished protein absorption, and higher levels of oxidative stress. Interestingly, in developing countries, vitamin A-deficient children who were treated with augmented dietary protein intake demonstrated an increase in serum retinol levels (Zalesin 2011). This supports the intimate interaction between serum retinol and the carrier proteins that determine the bioavailability of serum retinol concentration. As such, total body stores of vitamin A may not truly be deficient but, rather, low levels of nutritional protein binding transport capacity may underlie these serum retinol findings.

Cutaneous findings classically observed include follicular and keratotic papules that usually affect the anterolateral surface of thighs and arms. This condition is known as phrynoderma and may also be associated with other vitamin deficiencies. The lesions may overtake the extensor surface of upper and lower limbs, shoulder, abdomen, dorsal area, buttocks and neck. Other dermatologic signs of vitamin A deficiency include: xeroderma, brittle or corkscrew hair, and thinning of the skin (Jen 2010). A correlation between low plasma vitamin A and E and the subsequent development of acne has also been speculated (El-Akawi 2006).

Diagnosis is made based on serum retinol levels, clinical evaluation, and positive response to treatment. Normal serum retinol levels range from 28 to 86 $\mu\text{g/dL}$ (1 to 3

μmol/L). Levels, however, decrease only after the deficiency is advanced because the liver contains large stores of vitamin A. Therefore, when a deficiency is clinically suspected, a therapeutic trial of vitamin A may help establish the definitive diagnosis. Supplementation alone or in combination with other fat-soluble vitamins (D, E, and K) may be indicated in this setting. Current treatment recommendations are as follows: vitamin A palmitate in oil 60,000 international units (IU) orally once per day for two days, followed by 4500 IU orally once per day.

In summary, vitamin A deficiency remains an underreported postoperative complication of bariatric surgery. It is of paramount importance in the ongoing medical management of these patients that clinicians are aware of the cutaneous signs of retinol insufficiency. Furthermore, vitamin A deficiency should be suspected in those with protein-calorie malnutrition.

Vitamin B3

Vitamin B3 is converted to nicotinamide, a cofactor essential for cellular metabolism. In the intestine, the gut flora converts nicotinamide into nicotinic acid that is subsequently transported to the liver, kidneys and intestines. Sources of B3 include meat, poultry, nuts, eggs, fish, coffee and beans. Vitamin B3 is also synthesized in humans from the essential amino acid tryptophan. Pellagra, the classic triad of dementia, dermatitis and diarrhea, is the typical manifestation of vitamin B3 insufficiency. The dermatologic signs resemble a sunburn on the affected areas. A symmetrical eruption of scaling and skin thickening, with a clear margin between the unaffected and affected skin, is classically observed. The dorsal aspect of the hands is the most affected site and may present in a glove-like distribution. Additionally, the skin lesions may also be noted around the neck; this is denoted as Casal's necklace (Jen 2010) (Figure 1). Other skin manifestations linked to niacin deficiency include glossitis and angular cheilitis, sulfur flakes over the nose, and a copper hue to affected skin (Burke 2013). The patient may report that the rash burns or is intensely itchy. Histopathological changes in the acute phase include subepidermal vesicle formation as a result of spongiosis, ballooning degeneration, and vacuolar alteration of the basal layer (Hegyi 2004).

It is critical for clinicians to remain vigilant in assessing for vitamin B3 deficiency in patients that have undergone gastric bypass. The diagnosis can be made by measuring urinary N-methyl-nicotinamide concentration. Alternatively, low 5-hydroxyindoleacetic acid (5-HIAA), a metabolite of serotonin, may also be an indication of niacin insufficiency. Pellagra can be devastating to the patient but is, fortunately, easily reversed with replacement therapy. Complications such as delirium, depression, dilated cardiomyopathy, and, ultimately, death can be prevented by prompt recognition and implementation of vitamin B3 replacement. Dietary niacin, however, may not be sufficient to maintain the body's needs over an extended period of time (Leklem 1991). The recommended daily allowance is around 16mg per day for adult males and 14mg per day for females. Treatment is usually oral nicotinoamide (100-200mg three times daily) until signs and symptoms resolve after several weeks of therapy (Crook 2014).

Figure 1. Casal's necklace of pellagra. Courtesy of Ron Grimwood, MD.

Biotin

Biotin, a cofactor for carboxylase synthetase enzymes, is absorbed in the small intestine. It is essential in the metabolism of carbohydrates, fats, and select amino acids. Furthermore, it is critical for proper cellular function, growth, and development. Additional studies have also suggested that biotin may play a role in glucose metabolism at the level of gene expression (Rodriguez 2003). Likewise, biotin is crucial in immune function and cell proliferation. Humans cannot synthesize biotin and, therefore, must obtain this vitamin from exogenous sources (i.e., nutrition and intestinal bacterial synthesis). Dietary sources of biotin include egg yolks, liver, nuts, peanuts, mushrooms, cow's milk, and soy (Mock 2000; Lanska 2012). Deficiency occurs in patients with a short gut or malabsorption. The classic cutaneous finding associated with biotin deficiency is an erythematous, scaling, crusting dermatitis present around the eyes, nose, mouth, and perineal region. The tongue may also be red and sore, and the hair is commonly fine and thinned (Balint 1998). Diagnosis is made on clinical grounds based on the presenting dermatologic findings, as well as response to replacement therapy. If left untreated, acquired biotin deficiency may ultimately result in hyperaesthesia, paraesthesia, depression, and muscle pain. It is important for physicians to be astute in initiating a trial of biotin if clinical suspicion of insufficiency is high and the patient has a known risk factor such as a history of gastric bypass. A dose of 10-40mg per day orally, or intramuscularly, is the current recommendation for therapeutic replacement.

Vitamin C

In addition to serving as a cofactor in the synthesis of carnitine and catecholamines (dopamine and norepinephrine), ascorbic acid has anti-oxidant properties, stabilizes vitamin E and folic acid, and, also, acts as a cofactor for the enzyme that catalyzes the formation of hydroxylysine and hydroxyproline. Flaws in the synthesis of hydroxylysine and hydroxyproline secondary to vitamin C insufficiency interfere with collagen synthesis, thus, impairing wound healing. Additionally, ascorbic acid is part of the metabolism of prostaglandins and prostacyclins which, when inadequately produced, can generate decreased inflammatory response and increased immunological susceptibility (Jen 2010).

Dietary sources include citrus fruits, strawberries, tomatoes, vegetables and potatoes. Absorption occurs in the upper third of the intestine. Scurvy is the most classic consequence of vitamin C deficiency. This insufficiency, therefore, is often diagnosed by dermatologists. The clinical manifestations tend to occur one to three months after the start of a vitamin-deficient diet. The first signs are fatigue, malaise, and lethargy. The “four Hs” are characteristic of scurvy: hemorrhagic signs, hyperkeratosis of hair follicles (on the lateral and posterior areas of the arms buttocks, and thighs), hypochondriasis, and hematologic abnormalities. Perifollicular petechiae are also a characteristic finding (Fossitt 2009). The main changes in the oral cavity are the presence of edematous, erythematous, and friable gingiva with tendency to bleeding (Li 2008). Hansen et al. report a case of a woman following gastric bypass who presented with painful swelling, bruising, and small ulcers on her lower extremities (Hansen 2012). Within 24 hours, she developed confluent purpuric plaques on the lower extremities and a sepsis-like condition. The diagnosis of vitamin C deficiency was based on the clinical picture in conjunction with a positive response to supplementation. The daily recommended supplementation is ascorbic acid, 800-1000mg per day given orally for a few days to one week and maintenance of 100mg per day. In cases where the diagnosis is uncertain, serum ascorbic acid levels may be confirmatory.

In summary, following bariatric surgery, patients are at risk of developing vitamin C deficiency, especially if the operation is combined with a poor diet. When spontaneous ecchymosis or petechiae are observed in at-risk patients, scurvy must be included in the differential. While untreated scurvy may be fatal, the symptoms of scurvy rapidly improve when the patient is treated with adequate doses of vitamin C.

Iron

Iron is a mineral found in all cells of the human body. Dietary sources include dried beans, fruits, egg yolks, liver, beef, oysters, salmon, whole grains, broccoli, spinach, and kale. The majority of iron absorption is carried out in the duodenal epithelium. Acidity and the presence of solubilizing agents like sugars facilitate the intestinal absorption. Reduced gastric acid secretion after a gastric bypass, therefore, can impair the absorption of iron in the duodenum. Additionally, after Laparoscopic Roux-en-Y Gastric Bypass (LRYGB) the duodenum is excluded from digestive continuity, further impairing iron absorption (Ruz 2009).

Iron is essential for a multitude of functions including oxygen transport, DNA synthesis, energy metabolism, and metabolism of collagen (Richardson 1996; Polefka 2012). Iron plays

a critical role in the structure and function of skin. It aids in wound healing and protection against cellular damage secondary to reactive oxygen species. Exposure of skin fibroblasts to UVA can generate reactive oxygen species that promote oxidative damage in lysosomal, mitochondrial, nuclear, and plasma membranes. Ultimately, necrotic cell death will result due to the loss of plasma membrane integrity (Aroun 2012). As a transition metal which exists in two stable states, Fe^{2+} (electron donor) and Fe^{3+} (electron acceptor), iron plays a key role in preventing oxidative stress processes (Pelle 2011). Dermatologic manifestations of these effects are pallor, glossitis, koilonychia, angular cheilitis, and brittle hair and nails. Additionally, the tongue may become swollen and smooth and develop a burning sensation. Iron deficiency may also predispose one to bacterial and fungal infections, such as impetigo, boils and candidiasis (Jen 2010).

Obinwanne et al. performed a 10-year analysis of iron deficiency after laparoscopic Roux-en-Y Gastric Bypass (LRYGB) and reported an incidence of 53.1% (492 of 959 patients) (Obinwanne 2013). Furthermore, iron deficiency was more common in women, particularly those who were premenopausal or who had a history of abnormal uterine bleeding. According to the American College of Surgeons, female patients should be counseled that there is a 50% chance they will become iron deficient after LRYGB. Serum ferritin levels are assayed at three and six months postoperatively and then annually after the second postoperative year for those with initially low ferritin levels. Oral replacement is indicated if the patient has a postoperative ferritin less than 50 ng/mL and is administered in the following forms: ferrous gluconate, ferrous sulfate, ferrous fumarate, and ferrous bisglycinate. Oral iron therapy is limited after surgery due to decreased intestinal absorption (Mizon 2007). Another limitation of oral iron is that it is associated with significant gastrointestinal side effects that may ultimately lead to poor compliance. Common side effects include nausea, abdominal pain, diarrhea, and constipation. After a 3-month period of oral iron therapy, the ferritin level is assayed again. If it remains less than 50 ng/mL, the patient should be referred to the hematology clinic.

Indications for initiating intravenous (IV) iron therapy are poor tolerance of oral iron and poor response to oral iron treatment. IV iron treatment was required in 64 (6.7%) of the patients in the Obinwanne et al. study. The most commonly used form of IV iron was iron dextran (81.3%). This is largely because, unlike other forms, it is typically given as a single dose and does not require frequent visits to the hematology clinic. It is, therefore, the most cost-effective form of IV iron therapy. However, due to its association with rare, but serious, anaphylaxis, a test dose with premedication is recommended before infusion begins (Quinibi 2010; Defilipp 2013).

Iron deficiency is a problem that continues to cause complications in patients who have had gastric bypass. The aforementioned longitudinal study highlights the importance of strict postoperative follow-up of patients, with particular attention to those who may be at a higher risk for developing iron deficiency. Early detection of iron deficiency is key to the successful management of patients after gastric bypass.

Copper

Copper, a metal found in plasma, erythrocytes, cerebrospinal fluid, saliva, and gastric secretions, is obtained from the ingestion of meat, seafood, vegetables, grains, and nuts.

Copper is an essential cofactor in many enzymatic reactions vital to the normal function of hematologic and vascular systems. Additionally, copper has a crucial role in direct and indirect antibacterial mechanisms as well as early wound healing (Griffith 2009; Mirastschijski 2013). Many patients with an acquired copper deficiency have a history of gastric surgery, even in the distant past (Prodan 2009). The proposed mechanism of copper deficiency is likely due to the decreased absorption in the stomach and proximal duodenum. Consequences of copper deficiency may manifest clinically dermatologically as poor wound healing, depigmented and thinning hair, and alopecia (Palint 1998). Copper deficiency does not manifest as dramatically on the skin as other micronutrient deficiencies, but a high level of suspicion should remain because it may accompany other deficiencies. Approximately 70% of women may experience some level of copper deficiency after gastric bypass. Early detection and treatment can prevent the hematologic and neurologic symptoms such as pancytopenia and myeloneuropathy, respectively.

Diagnosis is based on low levels of ceruloplasmin and copper. These laboratory values, however, are not always accurate. Therefore, a positive response to supplementation may be the key in diagnosing the insufficiency. Treatment is usually in the form of copper sulfate 1.5-3mg per day given orally, but severe deficiencies may need to be replaced intravenously (Griffith, 2009).

Vitamin K

Dietary deficiency of vitamin K, a fat-soluble vitamin, is rare in adults because 50% of daily needs are synthesized by bacteria. Low vitamin K, however, may be seen in patients after undergoing malabsorptive procedures. Vitamin K is essential for the synthesis of several coagulation factors such as II, VII, IX, X, protein C, and protein S. Dietary vitamin K (phylloquinone) is found in green leafy vegetables, liver, brussel sprouts, lentils, plant oils, and soybeans. It is absorbed through active transport in the upper small intestine. The classic cutaneous findings secondary to vitamin K deficiency are related to the extravasation of blood into the skin manifested as purpura, petechiae, ecchymoses, and bruising (Jen 2010; Palint 1998). Clinically, it is important for physicians to be vigilant in investigating evidence of bleeding and bruising on the skin so as to prevent more severe and devastating hemorrhages.

Diagnosis is suspected based on routine coagulation study findings (prolonged prothrombin time or elevated international normalized ratio) and confirmed by a positive response to vitamin K administration. Some institutions may detect vitamin K deficiency more directly by measuring serum vitamin K levels (normal: 0.2-1.0 ng/ml). Vitamin K deficiency is typically treated orally, but, in the instance of fat malabsorption seen after bariatric interventions, intramuscular phytonadione 5-10 mg per day may be required.

Zinc

Bariatric surgery is a risk factor for developing a zinc deficiency. Zinc absorption occurs in the duodenum and proximal jejunum. It is these portions of the intestine that are bypassed in the RYGB procedure. Zinc is a primordial element essential to the structural and regulatory functions of over 200 enzymes. It can be found in most meat, legumes, whole grains, and

dairy products. Its key role is in metabolic pathways, mediating immune function, cell replication, and DNA synthesis. Overall, zinc allows for the proper function of T-cells, neutrophils, natural killer cells, and proper wound healing (Kumar 2012; Vick 2015).

Due to this mineral's extensive roles in a multitude of biological processes, many systemic and dermatologic complications may manifest in the setting of moderate to severe deficiency. The classic clinical triad is comprised of diarrhea, alopecia, and acral and periorifacial rashes. This rash tends to be symmetrical, erosive, and eczematous. Other cutaneous features include vitiligo-like lesions, delayed wound healing, paronychia, stomatitis, psoriasiform dermatitis, angular cheilitis, and blepharitis (Kumar 2012).

Diagnosis is generally made by serum zinc levels below 50-70 $\mu\text{g/dL}$ paired with recognition of the classic cutaneous findings (Krebs 2013). In cases of protein malnutrition experienced after surgery, there are changes in the intestinal structure and function with decrease in villi surface area culminating in a reduced capacity of zinc absorption. Moreover, it is likely that the decline in gastric secretion and the oxidative stress resulting from surgery also contribute to this diminished absorption of zinc. Ruz et al. studied the effects of zinc absorption in 56 morbidly obese women status post RYGB surgery. They measured mean plasma zinc, erythrocyte membrane alkaline phosphatase activity, and absorptive capacity of zinc. The percentage of absorption decreased significantly from 32.3% to 21% 18 months post-operation (Ruz 2011).

Figure 2. Perineal dermatitis of zinc deficiency. *Reprinted with permission* (Vick G, Mahmoudizad R, Fiala K. Intravenous therapy for acquired zinc deficiency secondary to gastric bypass surgery: a case report. *Dermatologic Therapy*; 2015. Wiley publisher).

If left untreated, zinc deficiency has the potential to be lethal. Typical treatment of acquired zinc deficiency consists of elemental zinc 1-3mg/kg orally once daily until symptoms and signs resolve. Serum or plasma levels of zinc should be monitored during administration of oral replacement. Cutaneous findings will clinically improve prior to a

significant change in serum levels. Additionally, copper levels should be monitored as high levels of zinc may lead to a reciprocal decrease in serum copper. Interestingly, Vick et al. reported a case of a woman who presented with a painful, pruritic vulvar rash despite 35mg of oral zinc replacement (Figure 2). The patient eventually had complete resolution of symptoms after two infusions of 2mg/kg per day of IV zinc. This highlights the fact that patients receiving malabsorptive procedures may not respond to traditional oral supplementation. Clinicians must be mindful of the fact that patients who have undergone structurally altering, malabsorptive surgeries may not respond to oral dietary supplementation, but rather require IV supplementation to resolve the consequences of the dietary insufficiency.

CONCLUSION

In summary, bariatric surgery has significant value in aiding patients who are unable to lose weight without surgical intervention to achieve drastic weight loss. Additionally, the literature provides ample evidence that this weight loss, combined with alteration of hormones and inflammatory mediators, results in reduced comorbidities of obesity including chronic, refractory dermatologic conditions such as psoriasis, necrobiosis lipoidica, acanthosis nigricans, and hidradenitis suppurativa. Along with the various benefits, risks and the potential for serious complications are inherent as well. Patients who have a recent or remote history of gastric bypass surgery are prone to a myriad of dermatological manifestations related to skin inflammation or impaired ability to promote proper wound healing. Even after vitamin and nutrient replacement therapy, however, clinical improvement may not be completely sustained. This highlights the dynamic nature of nutrient insufficiencies and the clinical manifestations that follow. Given the current obesity epidemic and steadily rising number of bariatric procedures performed each year, knowledge of these dermatologic complications secondary to micronutrient deficiency is essential to the clinician's ability to provide comprehensive care, and, subsequently, improve the patient's quality of life.

ABSTRACT

Bariatric surgery is currently the most effective and durable weight loss treatment for morbidly obese individuals with type 2 diabetes (T2D). In fact, up to 85% of individuals experience remission within days to weeks post-surgery, suggesting that the improvement in glycemia is independent of weight loss. Moreover, many individuals see improvements/resolution of their hypertension and hyperlipidemia in the months following surgery. Clinical trials indicate that the resolution of T2D in particular is maintained in approximately 40% of individuals 3-15 years post-surgery and highlights that over half of the people undergoing bariatric surgery may not meet diabetes remission criteria and/or redevelop the disease. Pre-operative clinical factors (e.g., age, fasting C-peptides, medication numbers, etc.) and gluco-regulatory mechanisms (e.g., insulin resistance, β -cell dysfunction) have emerged as clinically meaningful predictors of those who are likely to experience resistance to bariatric-induced diabetes remission. The management of individuals with T2D following surgery requires a personalized approach. Attention to lifestyle (i.e., diet plus exercise) should be the mainstay of therapy while attending to the risks of protein malnutrition and micronutrient and fat-soluble vitamin deficiencies. If these interventions are ineffective, pharmacological treatment in these patients will be an important consideration and should balance the need to control hyperglycemia with the risk of weight gain. A pharmacological approach may also include weight loss agents to combat obesity related insulin resistance and β -cell dysfunction. Collectively, these efforts are recommended to optimize clinical strategies that treat hyperglycemia following bariatric surgery.

INTRODUCTION

An estimated 347 million adults live with Type 2 diabetes (T2D) worldwide, about half of whom are undiagnosed [1]. Although the etiology of T2D is likely multi-factorial, nearly 80% of all people with T2D are obese, positioning obesity as a key modifiable factor in the development of hyperglycemia. The exact mechanism by which obesity, or excess body fat, induces T2D is an area of intense research. However, inadequate compensation of the β -cells in response to an increasingly insulin resistant skeletal muscle and liver characterize T2D and this is likely the principle cause. Indeed, patients with prediabetes have approximately 20% normal β -cell function remaining and have comparable degrees of insulin resistance to people with T2D [2]. In addition, adipose tissue is considered a chief culprit in the development of multi-organ insulin resistance and β -cell dysfunction through increased circulatory factors (free fatty acids, leptin, etc.) that promote hyperglycemia [3]. Newer understandings of T2D pathophysiology acknowledge that the gastrointestinal tract (e.g., small intestine), kidney, and central nervous system in addition to the aforementioned organs collectively play an important role in the progression to T2D. Thus, identification of end-organ targets that induce hyperglycemia is critical to the advancement of successful treatments strategies, as it seems focus on one tissue alone will not suffice in combating the rise in the diabetes epidemic.

Although controversial, the majority of health organizations consider obesity as a disease [4]. In either case, it is reasonable that current focus be placed on intensifying efforts to improve both weight management and glycemic control to combat the increased incidence of cardiovascular disease (CVD) in people with T2D. Here, we discuss studies relevant to addressing anti-obesity therapeutic options for the T2D individual as well as dual actions to improve glycemic control. To date the most effective treatment for obese people with T2D that induces substantial and durable weight loss as well as improved glycemic control is bariatric surgery. We refer readers to prior work for discussion on the Rouen-Y gastric bypass (RYGB) and sleeve gastrectomy (SG) procedures [5, 6] as here we summarize studies relevant to bariatric surgery as a gastrointestinal procedure that promotes favorable changes in β -cell function and insulin sensitivity for glycemic control. In addition, we present evidence suggesting that lifestyle modification directly and successfully induces meaningful weight loss and increase overall cardiorespiratory fitness, thereby highlighting exercise as a first-line therapy for the post-surgical patient. The present chapter also highlights recent advances in our understanding of pharmacological interventions that may in conjunction with lifestyle medicine drive weight loss and improve insulin sensitivity and β -cell function to maintain/improve diabetes care and obesity management. Lastly, we discuss potential role of these aforementioned treatments in an algorithm for the post-bariatric surgery patient to be considered in the optimization of health care and wellbeing.

TREATING T2D WITH BARIATRIC SURGERY

Several randomized trials confirm that bariatric surgery is an effective treatment that promotes T2D remission [7, 8] and contributes to durable weight loss in part by alternating gut hormones that regulate insulin metabolism (e.g., GLP-1 and ghrelin) [9, 10]. Subsequently, bariatric surgery has highlighted the gastrointestinal system as a key pathophysiologic mediator in the development of T2D. This is of particular clinical relevance given that bariatric surgery (in particular RYGB) improves survival when compared with matched controls [11]. While the literature is inconsistent with the definition of T2D remission, Ribaric and colleagues recently utilized the individual remission criteria of each study to report an overall remission rate of patients with T2D was 63.5% who underwent bariatric surgery compared to a rate of 15.6% with conventional therapy at a mean follow-up time of 17.3 months [12]. The results of this work indicate that people undergoing bariatric surgery are 9.8-15.8 times more likely to reach diabetes remission compared with conventional therapy. As a result of the collective impact of these studies and the literature, both the American Diabetes Association (ADA) and the International Diabetes Federation have identified bariatric surgery as an effective treatment for T2D [13, 14]. Indeed, data support the use of bariatric surgery as not only a weight loss treatment option, but also a “metabolic surgery” that restores glucose homeostasis in people with T2D. However, it is worth recognizing that not all people remain in T2D remission following bariatric surgery and insulin resistance as well as β -cell dysfunction appear to be key factors explaining the increased glucose levels [15-17]. It is not entirely clear why some people relapse to T2D post-surgery, but some work suggests a direct relationship between T2D relapse and years after surgery [7]. Most recently, a follow-up report to the Swedish Obese Subjects (SOS) study showed T2D remission rates decreased from 72.3% at 2 years to 30.4% at 15 years after surgery [18]. Moreover, long pre-operative T2D duration, insulin use, poor glycemic control despite oral hypoglycemic agents, inflammation, and microvascular complications are all additional indicators of inadequate β -cell function [16, 19]. Moreover, given the importance of sustained weight loss and prevention of weight regain in maintaining durable T2D remission, clinicians must be aware of the various factors that influence weight changes after surgery. Inadequate weight loss and weight regain is associated with non-adherence to lifestyle and dietary recommendations, pre-surgical weight variations, and surgical failure [20, 21]. Additional evidence suggests that surgery type may be associated with T2D re-emergence. Gastric restrictive procedures (e.g., SG) appear to be associated with higher weight regain and lower diabetes resolution rates than RYGB surgery, which may provide a basis for the differential T2D remission and re-emergence rates observed between bypass and restrictive surgeries [18, 22, 23]. Optimal weight loss therefore likely requires greater evaluation of each candidate with regard to their psychological history, as untreated depression, alcohol use, history of sexual abuse and eating disorders have been related to suboptimal weight loss [24, 25]. Indeed, a careful consideration of the benefits and risks of bariatric surgery should occur between clinician and patient prior to surgery such that lifestyle (e.g., exercise, nutrition, support groups, etc.) and/or pharmacology interventions may also be helpful in sustaining glycemic improvements. Thus, while bariatric surgery is a highly effective tool for promoting the reversal of T2D, it does not appear to be a treatment that “cures” T2D in all people. Additional work is required to determine appropriate treatment

plans with lifestyle modification or pharmacological therapy for preventing the relapse in T2D and weight regain [26].

POST-SURGERY CARE OF T2D: LIFESTYLE MODIFICATION

A central goal of obesity and diabetes care is to aid individuals in making better lifestyle decisions that lead to healthier body weights. Sedentary behavior and increased caloric intake are two key factors known to trigger insulin resistance and force the β -cell to secrete more insulin thereby over time leading to pancreatic exhaustion and hyperglycemia. In contrast, lifestyle intervention consisting of increased physical activity and low-fat diet inducing approximately 5 kg for 2 years or beyond lowers diabetes risk by 30-60% [27]. Interestingly, weight loss of 2-5% over 1 to 4 years decreases Hb_{A1c} by 0.2 to 0.3%. Moreover, losses of 5-10% at 1 year are associated with reductions in Hb_{A1c} of 0.6-1.0%. The Finnish Diabetes Prevention Study provided advice for subjects to lose >5% weight loss by decreasing total fat under 30% (with <10% coming from saturated fat), increased fiber consumption (i.e., 15g per 1000 kcal) and increased physical activity (30 min/d). This lifestyle prescription lowered the cumulative incidence of diabetes by 58% in people with prediabetes compared with controls [28]. In another landmark trial, the U.S. Diabetes Prevention Program (DPP) Study recommended adults with prediabetes to perform 150 min/wk and lose 7% weight loss. The DPP demonstrated that new diabetes cases were lowered by 58% with lifestyle treatment [29], although subjects who lost the most weight and met physical activity/diet targets had >90% risk reductions of T2D. These reports are consistent with recent work showing that the combination of a well-balanced diet (e.g., low fat and high fiber diet) promoting nearly 5-8% weight loss with increased physical activity is a well-established strategy for managing T2D as higher doses of physical activity generally increase insulin sensitivity [30, 31] and pancreatic function [32]. While caloric restriction is arguably the most important factor driving weight loss, it remains possible that low carbohydrate intake per se may yield greater reductions in circulating blood glucose and body fat, particularly during the first few months during the start of a lifestyle program [33, 34]. Nevertheless, increased physical activity is a primary determinant of maintaining the lost weight. As such, structured exercise interventions in particular have been shown to significantly improve Hb_{A1c} levels [35, 36]. But, whether exercise is effective at improving glycemic control in the post-surgical patient remains unclear, as some evidence suggests that not all people with hyperglycemia respond favorably to standard lifestyle interventions [37, 38] and additional work is needed to define the optimal exercise prescription that sustains lifestyle modification benefits in bariatric patients over time [39].

Although patients undergoing bariatric surgery report being highly motivated for future engagements in physical activities [40], few prospective exercise trials have been conducted following bariatric surgery to provide evidenced based medical practice. In fact, physical capacity and activity following bariatric surgery have been primarily investigated by questionnaire [41-45], pedometer [46], accelerometer [47, 48], or by a short physical performance battery test [44]. In general, the collective evidence suggests that increased physical function to perform daily activities occur with weight loss in bariatric patients [41, 44, 46, 49] as well as disease risk reduction (e.g., hypertension, T2D, etc.) [45]. However,

few studies exist objectively measuring cardiorespiratory fitness via whole-body maximal oxygen uptake (VO_2max). Interestingly, in the few studies reporting VO_2max , it was demonstrated that higher fitness levels prior to surgery were associated with decreases in short-term complication and hospitalization stay after surgery [50, 51] as well as increased physical activity post-surgery, which is linked to greater weight loss [20, 21]. Additionally, individuals with reduced physical limitations prior to surgery (defined as an inability to climb two flights of stairs) were associated with greater weight loss after surgery [52]. Thus, it seems clear that pre- and post-operative physical fitness of bariatric patients is clinically important, despite some reporting increased fitness is driven solely by weight loss [53].

Recently, a number of randomized controlled trials have been conducted to investigate the effects of exercise imposed on bariatric surgery to determine whether exercise can effectively promote greater weight loss, fitness, and cardiometabolic health when compared to a standard of care health education group. Shah and colleagues [54] demonstrated that a 12-week exercise program following bariatric surgery improved glucose tolerance. These findings are consistent with work by Coen and colleagues [55] highlighting that moderate intensity aerobic exercise increases insulin sensitivity and glucose effectiveness (i.e., the ability of glucose to facilitate glucose disposal), along with increased VO_2max and mitochondrial adaptation for fat oxidation during bariatric induced weight loss [56]. Indeed, others suggest that supervised endurance exercise or educational based programs with resistance exercise can facilitate greater weight loss, improved muscle strength and increased fitness capacity [54, 55, 57-59]. However, a limitation of the existing body of work is whether these effects of exercise on cardiometabolic health are maintained overtime, and whether exercise is an effective tool for the prevention of weight regain. These are important clinical questions that are likely to improve medical practice. Further randomized controlled trials are needed to define the optimal exercise prescriptions that provide additional health benefit as well as to elucidate mechanisms by which these improvements occur.

POST-SURGERY CARE OF T2D: PHARMACOLOGY

Despite randomized clinical trials showing the efficacy of lifestyle modification on weight loss and fitness, long-term adherence to diet and exercise remains difficult. While meeting glycemic goal with lifestyle interventions alone may be challenging for some post-bariatric patients, it is important to acknowledge there are no studies or guidelines to direct therapy in the post-bariatric surgery patient. However, if conventional approaches to improve glycemic control and weight with lifestyle do not work well, then pharmacological agents that target specific pathological defects contributing to insulin resistance, β -cell dysfunction and obesity may be necessary for T2D management in the post-surgical patient. As such, a reasonable pharmacological approach would be the one proposed by the ADA/European Association for the Study of Diabetes (EASD) [60].

Insulin Sensitizers

Metformin is the most widely prescribed drug to treat hyperglycemia in people with T2D [61]. In fact, metformin is the first-line oral anti-diabetic medication recommended by the ADA [62]. Current evidence suggests that metformin increases whole-body insulin sensitivity through the suppression of hepatic gluconeogenesis and stimulation of peripheral (mainly skeletal muscle) glucose uptake through activation of adenosine monophosphate-kinase (AMPK) [61]. Although considered weight neutral in most patients, for some patients with T2D and obesity, the use of metformin is of low cost and can promote weight loss [63]. To date, the longest and best study of metformin on body weight comes from the U.S. DPP. Within the first 3 years of this double-blind randomized trial, the metformin group lost approximately 2.9 kg vs. 0.42 kg in the control group [29]. Impressively, this weight loss effect has persisted up to 15 years [64]. Thus, metformin is a logical first-line pharmacotherapy for T2D to manage blood glucose and reduce body weight, although it is worth noting that interactions of metformin with lifestyle are an area of needed research. Studies report that metformin enhances, blunts or has no effect on exercise-induced improvements in insulin sensitivity and glucose homeostasis [61]. Whether there is an optimal combination of metformin with exercise and/or diet remains to be determined.

Of note, metformin is considered contraindicated by the FDA in the setting of renal disease due to a risk of metformin accumulation leading to lactic acidosis. The recommendations indicate that metformin should not be used when serum creatinine is 1.4 mg/dl or higher in women or 1.5 mg/dl or higher in men. In a review, Lipska and colleagues have nicely clarified the many issues raised by these recommendations and have made proposed adjustments to dosing based on estimated glomerular filtration rate, which is likely a better indicator of renal function [65]. Thus, caution should be used in patients at risk for acute kidney injury or significant fluctuations in renal status (e.g., potent diuretic use), based on prior history, comorbidities or drug interactions.

Thiazolidinediones (TZDs)

TZDs act on peroxisome proliferator-activated receptor (PPAR) γ , and are effective at improving both insulin sensitivity (e.g., adipose, liver and muscle) and increasing/restoring pancreatic β -cell function [2]. Despite these gluco-regulatory benefits, many physicians have concern about prescribing TZDs because they promote weight gain of approximately 2-5 kg. However, it is worth acknowledging that this fat storage is in part the mechanism by which TZDs increase insulin sensitivity and β -cell function. In fact, TZDs are known to lower circulating free fatty acid concentrations thereby lowering ectopic lipids (e.g., intramuscular fat) and visceral fat while distributing circulating free fatty acids to subcutaneous fat [66]. In addition, TZDs also have potent anti-atherogenic effects that may lower overall risk for CVD as well as delay the progression from prediabetes to T2D [67]. Thus, given the modest weight gain with this agent, TZDs should be considered as a second-line therapy for individuals who do not achieve glycemic control with metformin plus lifestyle modification.

A concerning side effect of TZDs include the increased risk of fracture, which was found to be increased in women in both the ACCORD trial [68] and in the

PROACTIVE trial [69] Given that more recent data has suggested a negative impact of bariatric surgery on bone metabolism [70] it may be prudent to avoid TZDs, particularly those known to be a high fracture risk (i.e., with osteopenia/osteoporosis).

Sulfonylureas (SUs)

SUs increase pancreatic insulin secretion through the binding of receptors related to potassium channels on β -cells [71]. Sulfonylureas are relatively inexpensive and easy to administer making them a popular choice for many patients. Utilization of SUs along with metformin may be prudent for those patients who experience T2D to prevent further β -cell failure. However, it was shown in the UK Prospective Diabetes Study (UKPDS) that SUs had no protective effect on the pancreatic β -cell in newly diagnosed T2D patients over the 15-year study [72]. In fact, blood glucose concentrations showed a continuous rise regardless of SU treatment when compared with control, and this decline in glycemic control was paralleled by a loss in β -cell function (estimated by HOMA- β). This is clinically concerning because by approximately 3 years of treatment, nearly 50% of people required additional pharmacological treatment to maintain Hb_{A1c} less than 7.0% [72]. Given that SU usage carries a risk of inducing hypoglycemia, does not preserve pancreatic function, has conflicting and potentially harmful cardiovascular risk and promotes weight gain compared with usage of oral insulin-sensitizing agents, SUs should be used with caution [71, 73].

Incretin Mimetics

GLP-1 (glucagon-like polypeptide 1) and GIP (glucose-dependent insulinotropic peptide) are incretin hormones that account for approximately 60% of the meal-stimulated insulin secretion, and are important for delaying gastric emptying and reducing post-prandial glucose levels by stimulating pancreatic function [74]. Some, but not all studies, suggest that a GLP-1 partial deficiency occurs in impaired glucose tolerance and in T2D, but there is no resistance to its action. There are two classes of medications- DPP-IV inhibitors that restore low GLP-1 to more normal levels and GLP-1 receptor agonists that directly bind to GLP-1 receptors with agonistic activity that is supra-physiological. As a therapy, GLP-1 targeted therapies have a degree of built-in safety because the insulin secretagogue effect is reduced when eu- or hypoglycemia is present. GLP-1 receptor agonists have two actions that are missing from the DPP-IV inhibitors- substantial appetite suppression with resultant weight loss of moderate degree in most patients and an ability to delay gastric emptying. GLP-1 receptor agonists are more effective in Hb_{A1c} reduction than DPP-4 inhibitors and they are not used in combination.

GLP-1 Receptor Agonists

There are 5 GLP-1 receptor agonists approved for the treatment of T2DM, including exenatide, exenatide extended-release, liraglutide, dulaglutide and albiglutide. Each has been modified to prolong the half-life of the molecule compared to native GLP-1, which has a half-life of minutes [75]. Given the capacity of GLP-1 to promote pancreatic β -cell function and

promote significant weight loss, many studies have highlighted the GLP-1 therapy as a novel approach to promote glycemic control and weight loss [76-78]. In addition, a recent meta-analysis suggests that GLP-1 receptor agonists provide more benefit to glycemic control than other anti-diabetic drugs added to existing metformin regimens [79]. Interestingly, studies looking at GLP-1 receptor agonist use with basal insulin suggest that the combination may provide greater glycemic efficacy than either component alone. In addition, the common side effects of nausea (GLP-1 receptor agonist) and weight gain (insulin) may be ameliorated by the combination [80, 81]. Cardiovascular safety trials are ongoing with these agents. Lixisenatide, not currently approved for use in the U.S., was found to be neutral in the ELIXA trial [82], but early reports from the LEADER trial with liraglutide suggest that there may be cardiovascular benefit. It should be noted that GLP-1 receptor agonists have been associated with an increased risk of pancreatitis and pancreatic cancer [83], although this has not been borne out in the published trials to date.

Dipeptidyl Peptidase-IV (DPP-IV) Inhibitors

DPP-IV is an enzyme that cleaves GLP-1, thereby limiting the gluco-regulatory benefits of this incretin hormones action. Inhibitors of DPP-IV act by increasing GLP-1 concentrations, and are dependent of endogenous GLP-1 secretion [84, 85]. This is physiologically relevant as DPP-IV not only attenuates β -cell function but also decreases insulin sensitivity in adults with metabolic syndrome [86]. While there is limited data on the long-term utility of DPP-IV inhibitors, several studies show that this class of pharmacological agents improve post-prandial glucose metabolism while maintaining insulin levels. Interestingly, this point is consistent with work demonstrating that lifestyle modifications lowers DPP-IV in relation to lowered CVD risk [86]. Nevertheless, DPP-IV inhibitors have no effect on weight loss, so this treatment regimen appears unique to glycemia per se and may not be appropriate for combating the obesity often associated with T2D during the post-surgery period. Currently, there are four DPP-IV inhibitors approved for use in the U.S. (alogliptin, linagliptin, saxagliptin and sitagliptin). Cardiovascular safety trials in high risk patients have been carried out with alogliptin, saxagliptin and sitagliptin in the EXAMINE, TIMI-SAVOR and TECOS trials, respectively [87-89]. All three agents were found to be safe in patients, but saxagliptin showed a signal for increased risk of hospitalization for heart failure (a secondary end point). The cardiovascular safety trial for currently in progress.

Insulin

Patients with less than adequate responses to oral or non-insulin injectable medications should be considered for treatment with basal and/or prandial insulin as necessary. Although insulin use carries risk of hypoglycemia and weight gain [90], evidence suggests that individualizing insulin titration in conjunction with oral pharmacological agents promotes better glycemic benefit compared to patients who do not respond to other oral agents. For instance, obese patients with insulin-requiring T2D after gastric bypass showed higher rates of complete remission at 1 year post-surgery with personalized insulin titration schedules and metformin compared with patients whose post-surgical medical care did not involve protocol-

driven pharmacological treatment [91]. Thus, the few studies that do exist suggest that combinations of existing T2D therapeutics can provide adequate glycemic control during the post-surgical period despite the tendency of insulin use to cause weight gain of 2-9 kg within 6-12 months of treatment [2]. It is important to keep in mind those patients with longer duration of T2D and/or insulin use prior to surgery may have relative insulin deficiency due to reduced pancreatic function. In these patients, initiation of insulin therapy should not be delayed.

Sodium-Glucose Co-Transporter 2 (SGLT2) Inhibitors

The kidney plays an important role in filtering approximately 160 g of glucose each day, and nearly 90% of all glucose is reabsorbed in the body by SGLT2 transporters located in the proximal tubule [2]. Novel data suggest that SGLT2 inhibitors, or gliflozins, are an additional anti-diabetes option that block glucose reabsorption in the renal tubules that in turn promotes loss of glucose in the urine. Canagliflozin, dapagliflozin and empagliflozin are the currently approved SGLT2 inhibitors approved for use in the U.S. for treatment of T2D. A meta-analysis of 25 randomized trials concluded that use of SGLT2 inhibitors for T2D is associated with significant improvements in glycemic control and blood pressure as well as reductions in body weight [92]. This is consistent with other work in patients with poorly controlled T2D showing that SGLT2 treatment as an add-on therapy to metformin improves many of these CVD risk factors [93]. A recent study of the use of empagliflozin in patients with T2D and high cardiovascular risk showed improved cardiovascular outcomes, driven mostly by reduced death due to cardiovascular causes [94]. Not surprisingly, a common side effect of the use of SGLT2 inhibitors includes risk of genital mycotic infections and lower urinary tract infections [95]. In addition, volume depletion and orthostatic hypotension can occur likely due to the osmotic diuresis induced with glucosuria. Finally, the FDA recently updated the labeling of canagliflozin to include a warning about an increase in fracture risk (seen as early as 12 weeks after initiation of the drug) and reduced bone density. The FDA is continuing to evaluate the fracture risk in the other medications in this class. Like TZDs, the use of SGLT2 inhibitors (especially canagliflozin) in the post-bariatric surgery patient should be approached with caution balancing the risks and benefits for each patient. Nevertheless, given the favorable effects of SGLT2 inhibitors on glycemic control, weight loss, and blood pressure, SGLT2 inhibitors constitute an attractive treatment modality to approach management of T2D, especially for obese patients suffering from hypertension.

Weight Loss Agents with Glycemic Benefit

Four new therapies have been approved for weight loss since 2012 and join orlistat for the long-term management of overweight and obesity. These therapies are generally recommended for obese ($\text{BMI} \geq 30 \text{ kg/m}^2$) individuals or overweight ($\text{BMI} \geq 27 \text{ kg/m}^2$) people who suffer from at least one weight-related complication, such as hypertension, T2D, or dyslipidemia. With the exception of orlistat, these medications act in the central nervous system to reduce appetite and increase. These agents have been recommended as important adjuncts to lifestyle modification [96] and may benefit those individuals with weight re-gain

after bariatric surgery. Many of these therapies have shown benefit in improving glycemic control.

Orlistat

Orlistat is a gastric and pancreatic lipase inhibitor that blocks dietary fat absorption from the gastrointestinal system by approximately 30%. Both randomized trials and meta-analyses have demonstrated that orlistat treatment can produce weight loss and reduce the incidence of T2D in people with impaired glucose tolerance [97]. A recent randomized controlled trial over 1 year reported greater weight loss and improvements in insulin sensitivity in patients treated with orlistat as compared with those treated with placebo [98]. Several mechanisms have been proposed to account for the anti-diabetic effect of orlistat, such as improved insulin sensitivity, incomplete dietary fat digestion, partial stimulation of GLP-1 release, and decreases in visceral adiposity [99]. However, orlistat intake is subject to fecal urgency, mild steatorrhea, and flatus with discharge, and the drug may interfere with absorption of fat-soluble vitamins [90]. As such, orlistat should be used with caution to ensure healthy nutrient intake for the patient.

Phentermine-Extended Release (ER) Topiramate

Phentermine is a sympathomimetic that reduces appetite by stimulating norepinephrine action in the hypothalamus. Topiramate is a carbonic anhydrase inhibitor and a monosaccharide that lowers food cravings, decreases lipogenesis, and increases energy expenditure. In the SEQUEL trial, which is an extension of the CONQUER trial, phentermine- combined with ER topiramate induced greater weight loss and HbA_{1c} improvements in patients with T2D with compared to patients treated with placebo alone [100]. In fact, study participants with prediabetes, metabolic syndrome, or both who underwent treatment with phentermine-topiramate had significant weight loss and lowered the progression to T2D [101]. Therefore, because phentermine-ER topiramate appears to induce beneficial effects on weight loss and glycemic control, it warrants consideration as a potential obesity related therapy for T2D.

Lorcaserin

Lorcaserin is a selective agonist of the serotonin 2C receptor. It activates central serotonin 2C receptors with a functional selectivity of approximately 15 and 100 times over that for serotonin receptors 2A and 2B, respectively. It reduces appetite and food intake thereby reducing body weight in men and women [102]. In a randomized trial called BLOOM-DM, 604 patients with T2D were randomly assigned to Lorcaserin (10 mg once daily or twice daily) or placebo, and the majority of patients were treated with metformin, a sulfonyleurea, or both. After one year, more patients lost $\geq 5\%$ of their body weight with Lorcaserin compared with placebo (44.7, 37.5, and 16.1%, respectively). There was also a significant reduction in HbA_{1c} (-1.0, -0.9, and -0.4% points, respectively) and fasting blood

glucose (-28.4, -27.4, and -11.9 mg/dL) in the Lorcaserin compared with placebo group [103]. Since Lorcaserin appears to affect both body weight and glycemic control, it appears to be an agent for promoting or maintaining weight loss in individuals. However, future studies are needed to clarify the efficacy of Lorcaserin in maintaining weight loss over time as well as blocking weight gain due to aging or other pharmacological agents (e.g., TZDs, insulin, etc.).

Naltrexone-Bupropion

The combination of naltrexone and bupropion (e.g., Contrave) is designed to target the mesolimbic dopamine reward system and the hypothalamic melanocortin system to reduce food intake. Naltrexone-bupropion induces significant weight loss as well as proportional reductions in fat mass and visceral adiposity [104]. In addition, Hollander and colleagues demonstrated that overweight/obese patients with T2D randomized to naltrexone-bupropion experienced significantly greater weight loss and improvements in HbA_{1c} levels following treatment when compared with placebo [105]. Although these results appear promising for combating both obesity and hyperglycemia in the T2D patient, caution at this time should be considered since attrition rates have been approximately 50% in current trials with the most common side effect reported being constipation, headache, vomiting and dizziness. As a result, further clinical research is warranted to understand the long-term safety and utility of this agent.

POTENTIAL RISKS OF BARIATRIC SURGERY AND CONSIDERATIONS

It is worth acknowledging that severe hypoglycemia has been documented after RYGB and is associated with post-prandial hyperinsulinemia due to elevated GLP-1 levels [106]. This hypoglycemia is classified as neuroglycopenia and seizures have been reported in rare circumstances. The conventional treatment of hypoglycemia in these patients involves carbohydrate restriction to minimize hypoglycemic related episodes and at times, requires reversal of the surgical procedure [107]. To that end, nutritional deficiencies also may occur in 30-70% of patients. Patients at high risk of developing severe nutritional deficiencies include those who have lost more than 10% of their body weight by 1 month, and those with: anastomotic stenosis, surgical revision requirements, and persistent vomiting [108]. Protein-calorie malnutrition is also a concern and can be recognized by signs such as edema, hypoalbuminemia, anemia, and hair loss. To minimize these effects, it is generally recommended that patients consume between 60-80 g/d of protein and approximately 800 kcal/d. Vitamin deficiencies can lead to peripheral neuropathy (B₁₂), Wernicke encephalopathy (B₁), and metabolic bone disease (Vitamin D). Subsequently, in addition to multi-vitamin supplementation, monitoring nutrient and vitamin levels after bariatric surgery is recommended at least every 6 months [108-110].

CLINICAL APPROACHES AND CONCLUSION

The re-emergence of T2D and cardiometabolic disease post-bariatric surgery occurs in approximately 30-70% of individuals. Optimal evidenced based treatment strategies for the obese person with T2D following bariatric surgery is currently lacking, but is likely going to relate to the underlying pathophysiology. In fact, the complicated etiology of T2D highlights that a number of therapeutic options will likely be required in order to correct varying disturbances with tissues (e.g., skeletal muscle, liver, adipose, gut, kidney, etc.) based on the persons age and pre-existing weight status. In this sense, it is prudent to select therapies based on the underlying cause of T2D re-emergence rather than purely on blood glucose concentrations. Moreover, monitoring earlier on in post-surgical process of the disease is likely to preserve β -cell function and restore insulin sensitivity for ultimate reductions in blood glucose and CVD risk over time. In fact, the available evidence and our clinical experience suggest that T2D is related to weight gain combined with the exhaustion of insulin-secreting pancreatic β -cells due to skeletal muscle, liver and adipose insulin resistance. While it is often reported that maintenance of this lower weight following exercise and diet is difficult due to strong compensatory mechanisms that promote feeding to restore energy balance, we propose that exercise and diet is successful at maintaining long-term weight loss and improves glycemic control in hyperglycemic individuals when performed at adequate “doses.” Thus, lifestyle modification should remain the first-line therapy for treatment of T2D. However, not all people are able to perform the necessary levels of physical activity needed to maintain metabolic health. As a result, we believe that pharmacologic intervention aimed at reducing weight and increasing insulin sensitivity (such as metformin, TZDs or canagliflozin), followed by treatments that promote insulin secretion if this initial treatment proves unsuccessful, are appropriate treatment strategies. In addition, several of these pharmacological agents (metformin, GLP-1 agonists, SGLT2, etc.) are a viable pharmacological agent for promoting modest weight loss in the obese individuals with T2D. Importantly though, it should be recognized that the quantity of weight loss following these pharmacological treatment plans are modest (1-5 kg) relative to the amount needed for most obese people to achieve healthy weight status and/or optimal glycemic control and CVD risk reduction. Thus, any one pharmacological agent is unlikely to be a sole anti-obesity agent, and these drugs should only be considered as an adjunctive therapy to exercise plus diet. As more patients may redevelop T2D following bariatric procedures, we will need improved understanding of ideal treatment modalities (i.e., metabolic fitness programs via lifestyle and/or pharmacology) to manage these individuals.

Chapter 144

GASTROINTESTINAL HORMONES AND ROUX-EN-Y GASTRIC BYPASS

Deniz Atalayer, PhD

Sabanci University, Istanbul, Turkey

ABSTRACT

Obesity is a multifactorial global epidemic with associated risk factors for an array of vascular, metabolic, psychological and economical consequences. Bariatric surgery offers the most effective results and Roux-en-Y gastric bypass (RYGB) is the most commonly performed bariatric surgery worldwide. The effective weight loss achieved by RYGB is thought to be caused by the re-arrangement of the gastrointestinal tract leading malabsorption and restriction of the ingested nutrients, and consequently resulting in alterations in the gut hormone levels. This review briefly summarizes the current literature on the changes in the gastrointestinal hormones following RYGB. Understanding these post-operative alterations may provide insights on the efficacy of RYGB that may help developing superior surgical techniques, novel pharmacological and psychological interventions, as well as prevention strategies against obesity.

INTRODUCTION

Obesity is a global pandemic however; weight loss achieved by pharmacological and behavioral treatments are generally ineffective in maintaining a healthy body weight over a longer period of time and thus usually followed by weight regain. Bariatric surgery is currently the most effective anti-obesity intervention (Sjostrom et al., 2004, 2007) in comparison with the non-surgical treatments (Gloyet al., 2013; Buchwald et al., 2004) inducing a negative energy balance by reducing food intake (Rubino et al., 2010) and increasing energy expenditure (Stylopoulos et al., 2009). It also has been shown to improve glucose homeostasis and resolve type-2-diabetes (T2D) (Sala et al., 2014). Roux-en-Y gastric bypass (RYGB) has been the most commonly performed procedure in the world and although there had been a marked decrease in the number of RYGB performed from 2003 to 2008 with

the co-morbid increase in the preference for sleeve gastrectomy, another bariatric surgery procedure, RYGB still remains the most commonly performed bariatric procedure worldwide in 2013 (Buchwald et al., 2009b, Angrisani et al., 2015).

During RYGB, a small proximal pouch (typically < 30 ml) is created from the stomach, which is attached to a segment of the jejunum that has been brought rostrally after being transected. The large gastric remnant is joined to the mid- to distal jejunum, creating the Roux-en-Y limb. RYGB causes restriction by reducing stomach capacity by ~95%, and re-directs the flow of nutrients, which results in ingested foods bypassing the 95% of the stomach, entire duodenum, and a small portion (15–20 cm) of the proximal jejunum (Cummings et al., 2004), passing the small re-sectioned stomach pouch directly being shunted into the mid- to distal jejunum. It has been reported that patients, after RYGB, often experience significant reductions in appetite, as well as greater satiety following the ingestion of smaller meals (Ashrafian et al., 2009). Several studies in humans and animals have shown that physiological changes in, i.e., intragastric pressure (Raybould 1991) and emptying rate (rats) (Kalogeris et al., 1983), as well as pyloric motility (Treacy et al., 1992), following nutrient delivery to different parts of the gastrointestinal (GI) tract. Moreover, the mechanoreceptors and chemoreceptors embedded in the lining of the GI tract respond to specific amount and type of macronutrients (Mei 1985). In RYGB, a re-arrangement of the GI tract is achieved; the nutrients bypass the duodenum and proximal jejunum and are being shunted directly into the mid jejunum. It is assumed that this re-arrangement causes alterations in the gut hormone responses, which may be contributing to the efficacy of RYGB on effective weight loss (Cummings et al., 2004). However, the specific mechanisms underlying the efficacy of RYGB are still under investigation. It has been reported that RYGB produces changes in the gut-brain communication regulating energy balance which then leads to reductions in subjective appetite and food intake causing weight loss of approximately 25–30% of total body weight (Sjostrom et al., 2007). The weight loss following RYGB has been shown to plateau after 1-1.5 years and to be maintained in most patients for at least 10 years following the surgery (Sjostrom et al., 2007). However, the degree of successful weight loss after RYGB varies considerably along with the remission rates. Thus, understanding the hormonal changes following RYGB may help elucidating the mechanisms underlying its success and lead to the development of novel preventative strategies and treatments with or without the surgical interventions.

GASTRIC SIGNALS

Gastrin, ghrelin and obestatin that are secreted by the stomach will be reviewed in this section.

Gastrin

Gastrin, a peptide of 34 amino acids, is secreted by G-cells that are located in the pyloric antrum and duodenum. It leads to the production of pepsinogen (an enzyme that breaks down the proteins) and stimulation of acid secretion in response to the expansion of the stomach or

ingestion of protein, caffeine, and alcohol (Posovszky and Wabitsch 2015). A direct anorectic or orexigenic effect of gastrin is not established so far. Earlier studies showed significantly reduced gastrin release postprandially at 3 and 12 months following RYGB (Schrumpf et al., 1981). Recent data also indicated lower postprandial incremental area under the curve (iAUC) with no changes for fasting levels of gastrin at 2 weeks post-RYGB (Jacobsen et al., 2012). Postprandial reductions in gastrin levels were also reported following a protein-rich meal in RYGB patients after 3 $\geq$ months post-operatively (Grong et al., 2015). Moreover significant reductions in gastrin cells in the excluded portion of the stomach in RYGB patients compared to the obese controls (Safatle-Ribeiro et al., 2013) have been reported at ≥ 3 years of follow-up. Taken together, these reports, along with similar findings from animal studies (Stenstrom et al., 2006), suggest a reduction in gastrin levels following RYGB.

Ghrelin

Ghrelin has been shown to be a major orexigenic hormone, mainly produced by the endocrine X/A-cells of the oxyntic glands of the stomach mucosa and released to the blood stream (Choi et al., 2003; Sakata et al., 2009; Thompson et al., 2004). Studies have also shown that its expression is highest in the stomach (Kojima et al., 1999) and to a lesser degree, in the pituitary gland (Howard et al., 1996) and the hypothalamus (Wren et al., 2000). Ghrelin rises prior to meals and declines rapidly postprandially (Carlson et al., 2009; English et al., 2002; Zwirska-Korczala et al., 2007), suggesting a role in preprandial hunger and meal initiation (Cummings et al., 2001). Moreover, ghrelin has been shown to have a circadian fluctuation in both animals and humans; it increases in the morning and decreases later in the day. Conditions of positive energy balance (e.g., hyperglycemia, insulin resistance, obesity) are associated with lower ghrelin concentrations (Shiia et al., 2002; Tschop et al., 2001). Obese individuals have lower fasting plasma ghrelin levels compared to lean people (Shiia et al., 2002; Tschop et al., 2001). However, the reduced levels of ghrelin in obese individuals do not appear to prevent further weight gain. The lower fasting ghrelin levels in obesity suggest a possible down-regulation of ghrelin in response to overeating or excess body weight. Higher ghrelin levels, on the other hand, have been observed during periods of fasting, hunger, or other conditions associated with negative energy balance, such as short-term starvation, cancer cachexia, as well as anorexia nervosa (Bloomgarden, 2007).

The major hypothesis regarding the success behind the RYGB had been the suppression of the secretion of the main orexigenic hormone ghrelin (ghrelin hypothesis) (Cummings et al., 2002). This was supported by the majority of the studies showing decreases in ghrelin levels following the surgery (Foschi et al., 2008; Frühbeck et al., 2004; Garcia de la Torre et al., 2008; Lin et al., 2004; Morinigo et al., 2004; Rodieux et al., 2008). However, results have been inconsistent; increases (Pardina et al., 2009; Holdstock et al., 2003; Vendrell et al., 2004, , Garcia-Fuentes et al 2008) as well as no change (Korner et al., 2009; Whitson et al., 2007a) in ghrelin levels have also been reported.

It is important to note that there are two major molecular forms of ghrelin; *octanoylated* (acyl) which comprises <10% of circulating ghrelin, and *des-n-octanoyl* (des-acyl) ghrelin, which have different, and perhaps opposing functions in relation to energy homeostasis (Toshinai et al., 2006; Zhang et al., 2005). Although the des-acyl form of ghrelin comprises more than 90% of the total ghrelin released (Hosoda et al., 2000; Leite-Moreira and Soares,

2007), the acyl (active ghrelin) is the portion that binds to the growth hormone secretagogue receptor-1A (Kojima et al., 1999) to regulate several metabolic processes and to promote food intake. Thus, it had become crucial to analyze the total, acyl and des-acyl ghrelin separately and therefore the assays distinguishing between acyl and des-acyl ghrelin moieties have been developed recently (Prudom et al., 2010). The reports using such assays support the initial ghrelin hypothesis showing significant reductions in the fasting levels of total and active ghrelin as well as postprandial (AUC) levels of active ghrelin at 2 weeks following RYGB (Jacobsen et al., 2012). Fasting and postprandial (AUC) des-acyl ghrelin levels were also shown to decrease in RYGB patients at 1-year follow-up (Nannipieri et al., 2013). Interestingly, studies indicated that both fasting and postprandial (AUC) total ghrelin levels following 1 and 3 months returned to pre-surgery levels at 1-year post-surgery follow-up (Peterli et al., 2012). Increases at 1-year post-op following an initial decrease have been consistently reported for total, active and des-acyl ghrelin during fasting and postprandially (Sundbom et al., 2007; Samat et al., 2013; Yang et al., 2014). It is possible that ghrelin decreases are transient after RYGB; and that ghrelin subsequently increases as weight loss continues due to lower food intake.

Obestatin

Obestatin is a 23-amino acid peptide hormone and is derived from posttranslational cleavage of preproghrelin, and released from the stomach (Zhang et al., 2005; Zhao et al., 2008). Although ghrelin is an orexigenic hormone, obestatin has been shown to have anorexigenic effects such as reducing food intake, delaying gastric emptying, and reducing body weight in rodents therefore antagonizing the orexigenic effect of ghrelin (Zhang et al., 2005). However, later, controversial findings have been reported on the effects of obestatin on food intake (Gourcerol et al., 2007; Lacquaniti et al., 2011). In humans, the common finding was that the fasting plasma obestatin was to be reduced in obese individuals compared to the normal-weight persons (Lippl et al., 2008; Huda et al., 2008; Guo et al., 2007) along with the findings showing lower ghrelin-to-obestatin ratio in obese vs. normal weight women (Vicennati et al., 2007).

A study reported a significant decrease in obestatin levels after a gastrectomy surgery (Huda et al., 2008) and studies investigating the changes in obestatin levels following RYGB have mostly been controversial reporting increases at 1-year (Yang et al., 2014) and 3-year (Martins et al., 2011), as well as no change at 2-year follow-ups (Roth et al., 2009).

FOREGUT SIGNALS

In this section, cholecystokinin (CCK) and glucose-dependent insulinotropic peptide (GIP) that are secreted by the duodenum and jejunum will be reviewed.

Cholecystokinin (CCK)

CCK was the first gut hormone found to be implicated in appetite control (Gibbs et al., 1973). It regulates gut motility, pancreatic secretion, and gall bladder contractions. It is secreted predominately from the I-cells in the duodenum and jejunum in response to the presence of nutrients in the intestinal lumen (Lieverse et al., 1994; Parker et al., 2005; Liddle et al., 1985). CCK regulates the digestive enzymes from the pancreas, stimulates gall bladder contraction, increases intestinal motility and inhibits gastric emptying (Liddle et al., 1985; Moran et al., 1994). Higher concentrations are associated with a reduction in meal size and meal duration. CCK has a short plasma half-life of a few minutes, plasma levels of CCK rise within 15 minutes after meal ingestion (Liddle et al., 1985) and enhance perceptions of fullness and reduce hunger during the course of a meal in both humans and animals (Kissilef et al., 1981; 2003; Gibbs et al., 1973). Fatty acids (with chain lengths of 12 or more carbons) and proteins stimulate CCK secretion (Holzer et al., 1994; Lal et al., 2004; Corp et al., 2003). It has been suggested that CCK signaling is a vagally mediated process between the gut and the brain. Supporting this, studies with animals showed that vagotomised rats do not show the lipid induced delay in gastric emptying or suppression in subsequent food intake (Moriarty et al., 1997). Moreover it has been shown that there is CCK-1 receptor expression in human vagal afferent neurons (Feinle et al., 2003).

Although CCK is involved in meal-termination, it does not appear to have an independent role in the long-term regulation of energy balance and body weight, but rather a primary role in short term control of appetite and satiety (Moran, 2000; Tadross and le Roux 2009). Thus, there had not been much interest in investigating CCK regarding a possible role in the efficacy of RYGB and are only few studies to date reporting on the changes in CCK levels following RYGB. Earlier studies compared postprandial CCK levels following RYGB showed that the CCK response was not affected (Rubino et al., 2004; Kellum et al., 1990). In addition, animal studies also lead similar findings: CCK was not significantly altered after RYGB-induced weight loss in rats, (Suzuki et al., 2005). However recent studies suggested some effects, at 1-week (Peterli et al., 2012) and 2-weeks (Jacobsen et al., 2012) following the surgery: the patients with RYGB had elevated postprandial maximum peak CCK levels with no difference for AUC concentrations. Thus postprandial CCK peak was increased, but the effect was short-lasting. Post-operative fasting CCK levels were also shown to be unchanged (Jacobsen et al., 2012). Although a reduction in CCK following RYGB might be expected due to the diversion of the ingested food away from its secretion site -the upper part of the small intestine (the duodenum), the jejunum also was shown to release CCK (Katsusuke et al., 2008), which may explain the unchanged AUC levels of CCK following surgery. However, the role of CCK in the efficiency of RYGB warrants further investigations.

Glucose-Dependent Insulinotropic Peptide (GIP)

Glucose-dependent insulinotropic polypeptide (GIP) is a 42 amino acid peptide and is proposed to have a role in the pathophysiology of obesity and type-2-diabetes (T2D). It is one of two well-known incretins (along with glucagon-like peptide-1; GLP-1) and synthesized in the enteroendocrine cells (K-cells) primarily in the proximal small intestine (duodenum and jejunum) and its secretion is induced by food intake, especially carbohydrate and lipid intake

(Nauck, 1986). Once released, GIP stimulates β -cells of the Islets of Langerhans to cause GIP secretion which gives it the property of an incretin. It also inhibits gastric acid secretion, suppresses lipolysis in adipose tissue, induces appetite and reduces energy expenditure in the brain (Paschetta et al., 2011). It promotes glucose absorption in the small intestine by increasing the number of GLUT1 glucose receptors (Creutzfeldt et al., 2001; Cheeseman 1996, 1998) and based on its effects on insulin secretion, GIP has been offered as a critical target for T2D treatments and etiology. Several studies have found that GIP (both basal and simulated) was elevated in obese compared to lean persons (VilSBoll et al., 2003) and severely blunted in patients with T2D (Saxena et al., 2010; Gautier et al., 2008).

In an RYGB procedure, the duodenum and a part of the jejunum are bypassed resulting in a lack of nutrient exposure (Rao and Kini, 2011). This rationale was agreed with the proponents of the foregut theory explaining the efficacy of RYGB, whereby bypass of the proximal small intestine leads to decreased anti-incretin effects. Thus, less GIP secretion was predicted following RYGB (Pories and Albrecht, 2001; Rubino 2008). However, results have been less consistent, with studies showing elevated (Lafarrere et al., 2007; 2008; Goldfine et al., 2007) or reduced (Rodieux et al., 2008; Korner et al., 2007), as well as unchanged GIP levels independent of weight loss (Cohen et al., 2007). Fasting GIP levels were reduced in diabetics but no change in non-diabetics who underwent RYGB at a 3-week (Rubino et al., 2004) as well as at 6- and 12-week (Clements et al., 2004) follow-ups. Furthermore, no change in non-fasting plasma GIP levels at 6-month follow-up in diabetic and non-diabetic RYGB patients have also been reported (Whitson et al., 2007a). Similarly, total postprandial iAUC GIP levels over a 4-hour period were significantly reduced in the non-diabetic RYGB patients compared to the gastric banding and non-operated controls (Rodieux et al., 2008) $\geq$ 9-48 months after the surgery. The most recent study by Xiong et al. (2015) showed that fasting and postprandial (at the 2-hour point) GIP decreased following RYGB at the 1-week and 1, 3, and 6-month follow-up periods gradually. However one limitation of this study is that in their sample they used a group of gastric cancer patients with T2D and or simple T2D. Thus their report may not be representative of non-diabetic obese nor T2D patients. However, in diabetic RYGB patients at a 1-month follow-up, postprandial GIP was found to increase 1.5 fold in response to 50 g glucose load (Laferrere et al., 2007; 2008). Another study also reported plasma GIP increases in hypoglycemic vs. non-hypoglycemic RYGB patients in response to a standard test meal (Rabiee et al., 2011). A possible explanation for the inconsistencies in the literature may stem from the nature of the GIP action. During this peak, the major insulinotropic effect of GIP is achieved at approximately 60 min after an oral glucose bolus and serum levels return to basal levels in approximately 120–180 min (Nauck, 1986). The short half life of GIP (Nauck, 1986) as well as the fast degradation following its peak after a bolus with only a small percentage left in the circulation however makes the detection and analyses of GIP in serum extremely difficult as well as unreliable. One group used whole blood GIP mRNA as a marker for systemic GIP gene expression to avoid the unreliability issues of measuring serum GIP (Moran-Atkin et al., 2013). In agreement with Lafarere et al.'s (2007; 2008) findings, they showed significant increases in GIP gene expression in correlation with the clinical amelioration of T2D following RYGB (Moran-Atkin et al., 2013). To summarize, the current literature suggest that GIP levels are elevated in persons with obesity and T2D which may contribute to insulin resistance and defective glucose-stimulated insulin secretion that are symptomatic in these conditions. Along with this, majority of the findings seem to agree with the notion that GIP decreases following

RYGB. Thus, GIP antagonism may be considered a target action for the therapeutic agents as decrease in GIP or a blockade in its action seem to be theoretically and preliminarily useful for obese persons and T2D patients. However, inconsistencies warrant further investigation.

HIND GUT SIGNALS

L cell-derived factors (peptide tyrosine tyrosine (PYY), glucagon like peptide-1 (GLP-1), GLP- 2, oxyntomodulin (OXM)), pancreatic signals (pancreatic polypeptide (PP), glucagon, insulin, amylin, somatostatin), and adipokines (leptin, adiponectin, resistin) will be reviewed in this section. GLP-1, GLP-2, OXM along with the pancreatic glucagon are products of proglucagon gene and known as proglucagon-derived peptides. However post-translational processing of proglucagon-derived peptides differs in a tissue-specific manner: glucagon is the main product in the pancreas, whereas GLP-1, GLP-2, OXM are the major products in the intestine and the brain (Posovszky and Wabitsch, 2015a; 2015b). PYY (PYY₁₋₃₆ and PYY₃₋₃₆) and PP almost exclusively expressed at the level of the digestive system (Cox, 2007; Holzer et al., 2012).

L Cell-Derived Factors

Intestinal L cells are open-type cells predominantly located in the distal ileum and colon and express fatty acid receptors (Pozowski and Wabitsch, 2015a). GLP-1, GLP-2, and OXM are cleaved from the precursor preproglucagon that is synthesized from the intestinal L cells along with PYY. Together, the L cell-derived factors are thought to mediate an ileal brake effect by reducing gastric acid secretion, gastric emptying and decelerating mouth-to-cecum transit time, and thus reduce food intake and prevent malabsorption and postprandial metabolic disturbances.

Peptide Tyrosine Tyrosine (PYY₃₋₃₆)

PYY is a 36-amino-acid peptide that has two circulating endogenous forms (PYY₁₋₃₆ and PYY₃₋₃₆) and one of the Neuropeptide Y peptide family, along with Y (NPY), and pancreatic polypeptide (PP) (Michel, 1998; Cox, 2007). PYY₃₋₃₆ is the biologically active form (Batterham et al., 2003a) and *originally isolated* from porcine intestine (Tatemoto, 1982). It is produced mostly in the small intestine and colon, released from the L-cells of the distal small bowel postprandially in proportion to the consumed calories. It is co-localized with proglucagon products, glicentin and glucagon-like peptide 1 (GLP-1) and GLP-2 (Ekblad and Sundler, 2002). It inhibits food intake (Batterham et al., 2002), increases energy expenditure (Guo et al., 2006) and delays gastric emptying (Sloth et al., 2007). PYY immunoreactivity is also found in the central nervous system regions such as the hypothalamus, medulla, pons, and spinal cord (Ekblad and Sundler, 2002; Kara et al., 2009). G-protein coupled Y receptor superfamily (Y1, Y2, Y4, Y5 and Y6) has specific affinities for each member of the peptide family; NPY and PYY do not grossly differ in their affinities for the Y1, Y2 and Y5 receptors

subtypes and PYY₃₋₃₆ preferentially binds to Y2 receptors (Cox, 2007). Endogenous PYY₃₋₃₆ levels were found to be low (Batterham et al., 2003a; Cummings et al., 2004; le Roux et al., 2006; Peterli et al., 2012) and blunted in obese individuals (Ashby and Bloom 2007), and increased in patients with anorexia nervosa (Misra et al., 2006).

Postprandial (AUC) PYY₃₋₃₆ levels were persistently elevated post-operatively at 2 weeks (Evans et al., 2012), at 1-month (Jacobsen et al., 2012), and 3- and 12-month post- follow-ups (Korner et al., 2009; Bose et al., 2010). At a 12-month follow-up, it has been reported that fasting and 3-meal 9-hour postprandial PYY₃₋₃₆ (AUC) levels did not differ between patients who lost 85% of their initial weight compared to the patients who only lost 35% of their initial weight (Dirksen et al., 2013a). However both group of patients had higher levels of AUC PYY₃₋₃₆ than the normal weight individuals showing that the increased levels of PYY₃₋₃₆ did not correlate with weight loss following surgery (Dirksen et al., 2013a). Similarly, postprandial peak for PYY₃₋₃₆ and AUC analysis for postprandial (OGTT) PYY₃₋₃₆ were found to increase significantly in RYGB patients at 1 month follow-up at 10% weight loss compared to the dieting group with the equivalent weight loss (approx. at 8 weeks) (Lafarrere et al., 2010). Regarding the fasting levels of PYY₃₋₃₆ several studies reported no change following RYGB at 2-week (Evans et al., 2012), 1-year (Bose et al., 2010) follow-ups, and with 7-10% weight loss levels (Plum et al., 2011). These implicate that the effect of RYGB on PYY₃₋₃₆ is not weight loss dependent and possibly related to the re-arrangement of the GI tract.

Glucagon Like Peptide-1 (GLP-1)

GLP-1 is mainly released by the L-cells of the small bowel following meal ingestion (Naslund et al., 2004; Feinle et al., 2003; Hermann et al., 1995; Doyle and Egan, 2007; Jang et al., 2007.) There are multiple circulating moieties of GLP-1: the biologically active forms, GLP-1₇₋₃₇ (comprising the 80% of the circulating GLP-1) and GLP-1₇₋₃₆ and the inactive forms GLP-1₁₋₃₇ and GLP-1₁₋₃₆. The active forms are powerful insulinotropics (i.e., they induce insulin secretion) (Schmidt et al., 1985). They act on the pancreas to secrete insulin (incretin effect) and also slow gastric emptying, inhibit glucagon release (Komatsu et al., 1989; Willms et al., 1996, Russell-Jones and Gough, 2012). GLP-1 is secreted in two phases; the first short rapid release occurs 5-10 minutes following a meal, and the later delayed and extended release occurs 30 to 60 minutes postprandially (Hermann et al., 1995; Ghatei et al., 1983). Thus, it is hypothesized that there are two distinct mechanisms of GLP-1 secretion. The initial phase, occurs when L-cells and K/L cells in the upper small intestine are in contact with the nutrients whereas the prolonged second phase occurs when L-cells in the distal bowel are activated (Rocca and Brubaker, 1999; De León et al., 2006). Thus, GLP-1 along with PYY may contribute to the “ileal brake” (Wen et al., 1995), an inhibitory feedback process of nutrients (specifically lipids) in the colon inhibiting motility and transit of further nutrients within the upper GI tract to optimize the meal digestion and absorption (Spiller et al., 1984).

Post-operatively, enhanced amounts of postprandial circulating GLP-1 (both maximum peak and AUC) with no change in the fasting levels, have been repeatedly shown, even when there is no significant weight loss (Peterli et al., 2009; Karamanakos et al., 2012; Bose et al.,

2010; Borg et al., 2006; Morinigo et al., 2006; 2008; le Roux et al., 2007; Korner et al., 2006; 2007; 2009; Laferrère et al., 2008; 2010; de Carvalho et al., 2009; Goldfine et al., 2007; Dirksen et al., 2010; Holdstock et al., 2008; Ochner et al., 2011). Furthermore, increased GLP-1 receptor signaling and GLP-1 secretion from the L-cells have also been shown (Mason, 1999; Gaitonde et al., 2012). The reduced size of the stomach and exclusion of the foregut, together allow for a faster delivery of food contents through the gut which may add to the dramatic increase in GLP-1 levels following RYGB. This is the ‘hindgut’ mechanism that has been proposed in explaining the efficacy of RYGB, whereby a direct flow nutrients to the distal small bowel causing an increase in the incretin effect. Thus the elevated levels of GLP-1 may contribute to the successful weight loss following RYGB in addition to the glucose homeostasis-related effects (i.e. T2D improvements and resolution) (Laferrère et al., 2008; Bose et al., 2009; Peterli et al., 2009). Based on these reports, it is likely that an earlier and enhanced increase in postprandial GLP-1 (and PYY₃₋₃₆) levels after RYGB may contribute to an early sense of satiety and reduced meal size (Santoro et al., 2008; Borg et al., 2006; le Roux et al., 2006; Rodieux et al., 2008) regardless of the reported unchanged fasting levels in both hormones.

Glucagon-Like Peptide-2 (GLP-2)

The 33-amino-acid peptide GLP-2, along with GLP-1, is also cleaved from the precursor proglucagon by intestinal endocrine L-cells (Rothenberg et al., 1995). However, unlike GLP-1, GLP-2 is not insulinotropic; does not inhibit insulin, but it is co-secreted with GLP-1 into the bloodstream in response to ingestion of lipids and proteins (Doyle and Egan, 2007; Jang et al., 2007; Matikainen et al., 2016). GLP-2 reduces gastric motility and acid secretion (Burrin et al., 2001), increases hexose transport, and in animals is shown to inhibit feeding (Tang-Christensen et al., 2000; Rotondo et al., 2011). However, there are only few studies to date that examined the changes in GLP-2 following bariatric surgery. In a study with obese persons with T2D, GLP-2 was shown to significantly increase postprandially (AUC) 6-weeks after RYGB (Romero et al., 2012). Another study comparing RYGB patients who are weight loss resistant and surgery patients achieving successful weight loss showed no changes in the fasting and postprandial (AUC) levels of GLP-2 at 1-year follow up (de Hollanda et al., 2014). However, although a statistical significance was not reached, an increasing trend for postprandial (AUC) GLP-2 was noted for the successful weight loss group (1354 ± 256 ng/mL) vs. weight loss resistant patients (658 ± 341 ng/mL, marginal means $\pm$ SD) (de Hollanda et al., 2014). Increased plasma GLP-2 was also shown following RYGB operation in rats (Le Roux et al., 2010). Based on its role in initiating intestinal epithelial barrier function and mucosal growth (Burrin et al., 2001; Holst 2010) GLP-2 may play a role in gut adaptation following RYGB to prevent malabsorption (Rhee et al., 2015).

Oxyntomodulin (OXM)

OXM is a 37-amino acid peptide originally isolated from porcine jejunoileal cells (Bataille et al., 1981). It is released from the gut in post-prandial state thus has anorectic effects. OXM is another product of the proglucagon gene and is co-secreted with GLP-1

and PYY by the L-cells of the distal intestines, in response to nutrient ingestion proportionally to the calorie intake (Ghatei et al., 1983). Laferrere and colleagues (2010) also showed that the increase of OXM was strongly correlated with total GLP-1 and PYY₃₋₃₆ after gastric bypass surgery. It was found that OXM shows glucagon-like activity in the liver (Bataille et al., 1982) and has a much lower potency when compared with GLP-1 (Schjoldager et al., 1988). OXM also inhibits gastric acid secretion and delays gastric emptying (Schjoldager et al., 1989). Administration of OXM is associated with decreased food intake and increased energy expenditure in both rodents and humans (Dakin et al., 2001; Cohen et al., 2003; Wynne et al., 2006; Maida et al., 2008).

Recently, few groups have investigated OXM levels following RYGB. Laferrere and colleagues (2010) reported enhanced levels of OXM (AUC and maximum peak) in response to oral glucose tolerance test (OGTT; 50g glucose load) 1-month following RYGB in morbidly obese women with T2D, which was not found in patients who achieved an equivalent weight loss by dieting. (Laferrere et al., 2010). A similar result was also reported by Le Roux and colleagues showing OXM increases following a standard breakfast postprandially (AUC) 6 months after RYGB (Werling et al., 2015). Another group have also reported slight OXM increases at 2-and 4-months following RYGB for postprandial levels (AUC) in response to OGTT and during fasting, however the effects were not statistically significant (Wu et al., 2013).

The proglucagon gene is also expressed in the intestines L-cells where it is cleaved into a number of peptides other than glucagon (i.e., GLP-1, GLP-2, OXM, glicentin) which were originally termed “enteroglucagon,” and are collectively known as “proglucagon-derived peptides.” Previous studies indicate that OXM makes up 30–40% of the plasma concentration of enteroglucagon in humans (Holst et al., 1983). Glicentin is a product of the proglucagon gene, and part of it is cleaved to generate OXM similar to GLP-1 (Sinclair and Drucker, 2005; Sala et al., 2014) and some researchers consider glicentin only a remnant metabolite of proglucagon after the cleavage of GLP-1 and GLP-2 (Sinclair and Drucker, 2005). Falken et al. (2011) reported a progressive rise in enteroglucagon at 3 days, 2 months, and 1 year following RYGB. Thus Falken et al. (2011) suggested that OXM may play an indirect role in the consequent weight loss.

PANCREATIC SIGNALS

The pancreatic endocrine cells are located in islets of Langerhans that contain four principal cell types, and are defined by the hormones they secrete. These include insulin and amylin-secreting β -cells (70%), glucagon-secreting α -cells (20%), somatostatin-secreting δ -cells, and pancreatic polypeptide-secreting PP-cells (originally termed F cells) (Fiocca et al., 1983).

Glucagon

Glucagon is produced by α -cells in the pancreatic islets of Langerhans and once released, binds to glucagon receptors in the liver initiating its critical role in glucose homeostasis by

increasing glycogenolysis and gluconeogenesis (Dunning et al., 2007). Glucagon, along with the intestinal GLP-1, GLP-2, OXM, glicentin, is synthesized initially as the protein proglucagon, which, in mammals, is encoded by a single gene. Decreases in food intake have been shown following glucagon administration both in animals (Martin and Novin, 1977) and humans (Penick and Hinkle 1961; Grossman 1986; Geary et al., 1992). It has been used as a therapeutic agent to treat severe hypoglycemia due to excess exogenous insulin administration, neonatal hyperinsulinism (Aynsley-Green et al., 2000), tumor-induced hypoglycemia (Chung et al., 1996), and severe post-RYGB hypoglycemia (Halperin et al., 2010). Elevated fasting plasma glucagon concentrations have been reported in severely obese individuals (Swarbrick et al., 2008).

Although the role of glucagon in glucose homeostasis is well established, so far the relationship between gut hormone responses and glucagon level changes following RYGB has not been extensively studied. Following RYGB (1-4 weeks post-surgery), fasting glucagon was reported to slightly increase (Swarbrick et al., 2008; Jacobsen et al., 2012; Jorgensen et al., 2012). Postprandial (with mixed meal test) glucagon has been found to be significantly higher 2 weeks following RYGB compared to the preoperative levels (Jacobsen et al., 2012) whereas this difference has not been found for glucose tolerance tests (25g and 50g). Lafarere et al. (2010) however found significant increases for AUC analysis of postprandial (OGTT; 50g glucose) glucagon at 1-month follow-up in RYGB patients compared to the dieting group with the equivalent weight loss (8 weeks). Using a mixed meal test, Campos et al. (2013) also reported that postprandial (AUC) glucagon increased at 2 weeks post-operatively however this did not persist and returned to the preoperative baseline levels at 6 months following RYGB. Similar results came from Jorgensen et al. (2012) showing postprandial (mixed meal) increases at 1 week after RYGB which declined and returned to baseline levels at 3 and 12 month follow-ups. Another study in obese patients with T2D also confirmed these findings that, fasting and postprandial (AUC) glucagon increased 2-4 weeks following RYGB which returned to the baseline levels at 3-, 6-, and 12-month follow-ups (Swarbrick et al., 2008; Nannipieri et al., 2013). However, in an earlier study, glucagon values were still found to be higher during mixed meal test in RYGB patients after 2-4 years following the surgery compared to the obese controls (Goldfine et al., 2007). It should be noted that Goldfine et al. (2007) used a cross-sectional study design study that may affect the results based on a possible lower baseline glucagon levels of the obese controls at the time of the study compared to the preoperative baseline glucagon levels in RYGB patients. Thus, based on the previous longitudinal studies, it is a stronger assumption that glucagon has an excursion at short-term after RYGB and a long-term decrease after a substantial weight loss.

Insulin

Insulin is one of the principal hormones involved in glucose metabolism and is synthesized in the β -cells of the pancreas and rises rapidly after a meal, with well characterized optimization of glycaemic index (Polonsky et al., 1988). Insulin resistance –a key feature of T2D (along with the subsequent hypoinsulinemia followed by hyperglycemia) is defined as the reduced sensitivity to the metabolic actions of insulin on glucose

homeostasis in the muscles and fat tissue or the suppressed hepatic glucose production in the liver (Rask-Madsen et al., 2012; Kahn et al., 2014). Insulin concentrations vary directly with body fat and insulin sensitivity is negatively correlated with body adiposity (Despres and Lemieux, 2006) and reductions of fasting insulin have been well documented following weight loss (Schwartz and Seeley, 1997).

RYGB has been suggested as a potential treatment for T2D as an alternative to pharmacological agents and meta-analyses and longitudinal studies report that that 60-80% of the RYGB patients show a complete resolution of T2D markers such as lower insulin sensitivity and resistance as well as blood glucose levels (Ferrannini et al., 2009; Buchwald et al., 2009a; Adams et al., 2012; Edholm et al., 2013; Yip et al., 2013). Fasting insulin and insulin resistance have been found to lower following RYGB in obese adults (Rodieux et al., 2008; Plum et al., 2011; Jacobsen et al., 2012; Peterli et al., 2009; 2012; Nannipieri et al., 2013) and adolescents (Oberbach et al., 2014). Postprandial (AUC) insulin following a mixed meal was shown to significantly decrease at 1-year follow-up whereas this was not shown at 2 weeks following the surgery (Nannipieri et al., 2013). However, Korner and colleagues reported greater insulin sensitivity and lower insulin resistance (HOMA-IR) following a intravenous glucose tolerance tests (IGTT) and fasting insulin levels in patients who underwent RYGB compared to persons who lost equal amount (7-10% weight loss) of weight by dieting (Plum et al., 2011). Campos et al. (2013) used a more accurate technique (Borai et al., 2011) of hyperinsulinemic euglycemic clamp to measure insulin sensitivity. They found that the average steady-state insulin concentration during the final hour of the euglycemic–hyperinsulinemic clamp decreased significantly in the morbidly obese non-diabetic RYGB patients 2-weeks after surgery, but was unchanged in the dieting group. Moreover, at the 6-month follow-up, when substantial weight loss has been reached, the decrease in steady-state insulin concentrations during clamp persisted, relative to pre-operative values (Campos et al., 2013). In agreement with this, 1-year changes in insulin sensitivity were shown to correlate with the corresponding changes in body mass index (BMI) following RYGB (Nannipieri et al., 2013). Thus, the early changes seem to be weight loss-independent.

Pancreatic Polypeptide (PP)

PP, the other member of the Neuropeptide Y Fold Family, is synthesized by endocrine PP cells in the pancreatic islets of Langerhans. It is secreted in response to a meal (Ekblad and Sundler, 2002), exerting anorexic effects in humans (Batterham et al., 2003b) by a mechanism through the parasympathetic vagus nerve (Asakawa et al., 2003; Cox, 2007; Field et al., 2010). The anorectic effects of PP are abolished by vagotomy in rodents (Asakawa et al., 2003). Its role in inhibits gastric emptying which may in part account for its ability to reduce appetite (Murphy and Bloom, 2006; Field et al., 2010).

In RYGB patients, fasting PP was shown to have a strong tendency to decrease at 2 weeks (Jacobsen et al., 2012; Campos et al., 2013), which was found to be significant at 1-month and 1-year follow-ups (Swarbrick et al., 2008). One study with T2D patients who underwent RYGB showed significant increases in fasting PP at 2-week which persisted at 1-year follow-up independent of the T2D remission (Nannipieri et al., 2013). However, the same study also showed marked reductions in postprandial (AUC) PP levels at both 2-week and 1-year follow-ups (Nannipieri et al., 2013). Others reported similar findings for non-T2D

RYGB patients 2 weeks after the surgery (Swarbrick 2008; Campos et al., 2013) and at the 12-month follow-up (Dirksen et al., 2013a).

Amylin

Islet/insulinoma amyloid polypeptide (IAPP, amylin) is a 37-aminoacid secreted hormone that was discovered (Westermarck et al., 1986) to be co-secreted with insulin from the β -cells within the pancreatic islets of Langerhans with a molar ratio of approximately 15:1 (insulin:amylin) (Hay et al., 2015) in response to blood glucose levels (Kahn et al., 1990). Amylin has been shown to inhibit insulin-stimulated glucose metabolism and muscle glycogen synthesis, and to slow gastric emptying (Hay et al., 2015). It is considered a satiety hormone (Lutz 2005) based on its short-term effects lowering food intake mainly via reducing meal sizes that is possibly through the central mechanisms within the hypothalamus and brain stem (Rowland et al., 1997; Lutz and Meyer 2015). Similar to leptin and insulin, number of experiments suggests a role for amylin as an adiposity signal affecting eating behavior by enhancing the anorectic effects of CCK (Mollet et al., 2003) and obesity was shown to be associated with high levels of amylin (Nannipieri et al., 2013). Administration of pramlintide, a synthetic analogue of human amylin, has been shown to improve glycaemic control and decrease body weight in T2D patients (Thompson et al., 1998; Schorr and Ofan, 2012; Weinzimer et al., 2012) suggesting a role for amylin in glucose mechanism and body weight regulation in humans.

Several studies reported decreased fasting and postprandial amylin (AUC) levels following RYGB at 1-year follow-up (Bose et al., 2010; Nannipieri et al., 2013). However reports on the 2-week follow-up have shown no change in amylin levels (Nannipieri et al., 2013; Jacobsen et al., 2015). Bose et al., (2010) reported significantly reduced fasting and postprandial amylin levels at the time when patients reached at least a weight loss of 12kg. These results seem to be in line with the notion that amylin may be considered an adiposity signal. Consistent with this, a recent study showed an association between BMI decreases and lower levels of total amylin in adolescents (Jensen et al., 2015). However most of the studies investigating amylin had been on preclinical models and further investigation is needed to fully understand its mechanism of action in humans.

Somatostatin

Somatostatin is mainly produced in the pancreas but also in the hypothalamus and in the D-cells of the GI tract exerting inhibitory functions and thus decreases the release of GI hormones and appetite (Barkan et al., 2003). Somatostatin analogs were shown to significantly reduce postprandial sensations of fullness in obese humans after a satiating meal without altering the tolerated maximum meal volume or postprandial gastric volume, suggesting an effect on the upper gut sensation but not directly on satiety regulation (Cremonini et al., 2005). Few studies assessing somatostatin showed no change following RYGB during a fasted state (Falken et al., 2011; Jacobsen et al., 2012) and postprandially (AUC) following an OGTT (50g glucose) or a mixed meal (Jacobsen et al., 2012). Statistical

significance was reached for AUC levels in response to 25g glucose load for the same study (Jacobsen et al., 2012).

ADIPOKINES

The adipokines are cytokines that are secreted by adipose tissue. Leptin was the first adipokine that was discovered (Zhang et al., 1994) and is released by the white adipose tissue (WAT).

Leptin

Leptin is an anorexigenic hormone and involved in long-term energy balance primarily by acting on the hypothalamus to decrease food intake and to increase energy expenditure (Beckman et al., 2011). It is secreted predominantly by the adipocytes with circulating levels proportionally to the fat mass in the body (Considine et al., 1996) and was observed to be higher in obese (vs. lean) persons during fasting and postprandially (Carlson et al., 2009; Carroll et al., 2007). Thus, perhaps it is not surprising that decreased leptin levels have consistently been reported following RYGB (Molina et al., 2003; Nijhuis et al., 2004; DePaula et al., 2009; Korner et al., 2009; Stoeckli et al., 2004; Kotidis et al., 2006; Shak et al., 2008; Faraj et al., 2003; Rubino et al., 2004; Lafarrere et al., 2010; Woelnerhanssen et al., 2011; Terra et al., 2013; Youssef et al., 2014), and all bariatric surgeries irrespective of the surgery type (Frühbeck et al., 2002; Cigdem et al., 2011; Knerr et al., 2006; Garcia de la Torre et al., 2008).

Adiponectin

Adiponectin or adipocyte complement-related protein of 30 kDa is a circulating protein and like leptin, secreted predominantly from the adipose tissue and is highly abundant in the plasma. However, unlike leptin, adiponectin levels remain relatively constant throughout the day and are not affected by food intake (Arora et al., 2006) and inversely correlated with body fat percentage in adults (Ukkola and Santaniemi, 2002) and BMI (Vendrell et al., 2004). Lower plasma levels of adiponectin have been reported in obese individuals with T2D compared to the non-diabetic obese individuals (Vendrell et al., 2004; Garcia de la Torre et al., 2008), suggesting a role in insulin resistance.

Following RYGB, adiponectin has been consistently shown to increase (Holdstock et al., 2003; Vendrell et al., 2004; Garcia de la Torre et al., 2008; Faraj et al., 2003; Whitson et al., 2007b; de Carvalho et al., 2009). To date, many clinical and, preclinical studies, as well as in vitro analyses indicated an involvement of adiponectin in glucose regulation and fatty acid oxidation, thus an association between insulin sensitivity and circulating levels of adiponectin (Fruebis et al., 2001; Diez and Iglesias, 2003; Scherer et al., 2013; Yamauchi et al., 2013; Kadowaki et al., 2014). This suggests adiponectin as a potential biomarker for insulin resistance (Scherer et al., 2013; Yamauchi et al., 2013; Kadowaki et al., 2014; Li et al., 2012).

Resistin

Resistin is a one of the family of cysteine-rich resistin-like molecules (RELMs) produced by adipocytes and immune competent cells (Steppan et al., 2001a; Holcomb et al., 2000). It was discovered as a secreted product of murine adipose tissue and shown to positively correlate with body weight in animals and to be suppressed by antidiabetic drugs (i.e., thiazolidinedione) (Steppan et al., 2001b). Upon its discovery and regarding its link with inflammation, resistin also was termed FIZZ3 (found in inflammatory zone 3) related to a protein induced during lung inflammation known as 'found in inflammatory zone 1' (Holcomb et al., 2000). Resistin has been mostly studied in animals (Rabe et al., 2008; Won et al., 2009; Rajala et al., 2004; Singhal et al., 2007; Osawa et al., 2008) and is commonly associated with insulin mechanism: higher resistin was speculated to contribute to insulin resistance (Vendrell et al., 2004) and administration of exogenous resistin was found to result in impaired glucose tolerance and insulin resistance in mice (Steppan et al., 2001a).

Numerous studies suggested an association between increased serum resistin levels and obesity, as well as visceral fat (Degawa-Yamauchi et al., 2003; Matsuda et al., 2004; Vendrell et al., 2004; Pagano et al., 2005), insulin resistance (Malo et al., 2011) and inflammatory markers (Vendrell et al., 2004; Luis et al., 2010) in humans. In a study with children, significantly elevated resistin levels have been reported in children with metabolic syndrome compared to obese children without the metabolic syndrome or the healthy controls (Makni et al., 2013). However inconsistent results exist reporting lack of such correlations between resistin and body weight (Chen et al., 2005; Utzschneider et al., 2005; Won et al., 2009; Rabe et al., 2008; Koc et al., 2011) or insulin sensitivity (Pagano et al., 2005; Utzschneider et al., 2005).

The highest levels of murine resistin have been shown to be expressed in white adipose tissue (i.e., highest in the gonadal adipose tissue) (Steppan and Lazar, 2002). However, human resistin in adipose tissue is significantly lower and almost undetectable. It was shown to be expressed at the highest level in the bone marrow followed by the lung (Patel et al., 2003) with mRNA found in the nonfat cells of adipose depots (Fain et al., 2003) as well as in human placenta (Yura et al., 2003). The discrepancies between the reports may be due to the molecular and genetic diversity between human resistin with its murine counterpart (Steppan and Lazar, 2004). Thus, whether the physiology of mouse resistin is pertinent to humans needs to be determined.

Although there had been implications suggesting a possible role for resistin in the mechanism for the resolution of T2D following bariatric surgery, few studies investigated the alterations in resistin following RYGB in humans (Vendrell et al., 2004; Whitson et al., 2007b; Lee et al., 2011). One study showed no change in resistin levels in morbidly obese patients following gastric bypass at 6-month follow-up (Vendrell et al., 2004). However, they found that preoperative resistin levels were predictive of the extent of weight loss following RYGB (Vendrell et al., 2004). A study in nondiabetic RYGB patients showed a significant increase in resistin after 6 months following the surgery compared to the preoperative levels (Whitson et al., 2007b). However, the small sample size ($n=4$) weakens the results of this study. Furthermore, Lee et al. (2011) reported lower fasting plasma and postprandial (AUC following a 3-hour mixed meal tolerance test) resistin levels after 2 years following RYGB. Although there was not a preoperative baseline comparison, the intriguing aspect of this study was that they reported that the weight loss at the 2-year follow-up was similar between

RYGB and sleeve gastrectomy patients however there was a significant difference in T2D remission in RYGB compared to the sleeve gastrectomy (81% vs. 19%). Thus the investigators suggested that resistin played a role in T2D resolution (Lee et al., 2011). Taken together, although a link between resistin and T2D has been reported, the normal physiologic role of resistin is still unclear, and the target tissues and molecular mechanisms by which resistin modulates glucose homeostasis require further investigation.

OTHER FACTORS RELATED TO GI TRACT

The alterations in the gut hormones caused by the rearrangement of the gut leading restriction and malabsorption of the nutrients following RYGB have been long suggested to be the major factor behind the success of RYGB leading weight loss and T2D resolution (i.e., the BRAVE effects of RYGB (Bile flow alterations, due to exclusion of the biliary limb, Reduced gastric size, Anatomic gut rearrangement, Vagal alterations secondary to the gut rearrangement, and Enteric (gut) hormone alterations). In addition to the BRAVE effects, recently, it has been suggested that the altered nutrient flux in the GI tract after RYGB might have different effects on the gut microbiota profile along the intestine. Accordingly, numerous studies have been conducted suggesting that the modulation of the gut microbial physiology to be responsible for the outcomes on energy homeostasis and metabolic function following RYGB (Erim et al., 2008, Papasavas et al., 2008). A few studies have examined the post-operative morphological changes following RYGB. Increased cell proliferation and downregulated apoptosis have been shown in the excluded gastric mucosa of the RYGB patents post-operatively compared to the non-operated obese controls (Safatle-Ribeiro et al., 2013). Such morphological and cellular alterations may be linked to changes in the number and function of enteroendocrine cells leading to increased plasma hormone levels after bariatric surgery.

CONCLUSION

Obesity is an epidemic and bariatric surgery is currently the most effective anti-obesity intervention and although the preference rate has been decreased, RYGB is still the most commonly performed bariatric surgery worldwide. However, the complete understanding of the mechanics behind the operation is still under investigation. It has been proposed that the anatomical re-arrangement alters food passage dynamics, evoking changes in gut hormone secretion to food that plays a major role in the efficacy of RYGB. During RYGB, a shortcut to the distal small intestine is created causing the bulk of foods passing into the small intestine without hindrance and a prolonged transit in the small intestine is achieved (Dirksen et al., 2013b); the stomach and chyme are restricted, and excluded from the foregut making the operation both restrictive and malabsorptive in nature. Overall, anorexigenic GLP-1, PYY₃₋₃₆ (Ochner et al., 2011) and orexigenic ghrelin (Ybarra et al., 2009; Sundbom et al., 2007) have been the most intensively studied gut hormones following RYGB and are considered to be the best candidates for explaining the reductions in food intake and a consequent extensive weight loss. Caution must be always applied regarding the factors such

as sample size, ethnicity, methodology (i.e., assay type, test meal load etc.), and obesity category, when interpreting the inconsistencies in findings regarding the gut hormone changes. Thus, contributions of reviews on the subject would prove to be very crucial for the field to have meaningful comparisons. Moreover, the physiological changes after RYGB are unlikely to be due to a single hormone, or single mechanism, but are more likely to due to the complex interplay between the gut hormones as well as the gut-brain communication that has not been reviewed here. Thus, new information is needed on the contribution of the different GI sites in reducing appetite and food intake in addition to its interactions with central systems on energy homeostasis and eating behavior. This will provide better understanding of the efficacy of RYGB on weight loss and may help to develop novel anti-obesity interventions to stimulate GI tract regions without surgery.

Chapter 145

BARIATRIC SURGERY ALTERS GUT METABOLISM: ROLE IN OBESITY AND TYPE 2 DIABETES RESOLUTION

Steven K. Malin, PhD

Department of Kinesiology, Division of Endocrinology and Metabolism,
Department of Medicine, University of Virginia, Charlottesville, VA, US

ABSTRACT

Bariatric surgery has revealed a significant link between gastrointestinal metabolism and obesity that extends to resolution of many metabolic diseases including type 2 diabetes and cardiovascular disease risk. Much of this beneficial metabolic health effect of bariatric surgery can be ascribed to weight loss. However, type 2 diabetes remission occurs within days post-surgery, such that it is likely independent of weight loss. This clinical observation has raised the possibility that altering gastrointestinal anatomy creates rapid metabolic responses that confer normalization of glucose tolerance. The exact mechanism by which bariatric surgery elicits favorable glucose changes remains unclear, but a leading hypothesis is that re-routed nutrient flow to the gut alters entero-endocrine (e.g., GLP-1, PYY, ghrelin, etc.) hormone production, circulating bile acid levels, and gut microbiome metabolites (e.g., LPS, SCFA, etc.) that favor appetite suppression, metabolic rate, and insulin sensitivity as well as β -cell function. While there is little work in the post-operative period describing the impact of lifestyle modification and/or pharmacology on gut metabolism post-bariatric surgery in men and women, the collective evidence provides strong support for an essential role for the gastrointestinal tract as a modulator of obesity-related disease. Thus, the gut is now considered a novel endocrine organ and a therapeutic target for prevention and medical approaches that favorably prevent and treat obesity related metabolic disorders.

Keywords: incretins, appetite-hormones, gut microbiome, bile acids, insulin resistance and secretion

INTRODUCTION

Lifestyle modification, consisting of exercise and diet, is the primary medical treatment for inducing weight loss and preventing the progression to type 2 diabetes. However, the magnitude and long-term adherence of this weight loss remains low, and with development of hyperglycemia, many people turn to exogenous compounds (e.g., pharmacological/dietary supplement tools) to manage their health. Unfortunately, the durability of these approaches does not typically work well over time in most individuals, and β -cell function declines such that glycemic control worsens. To date, the most effective treatment for obesity that induces substantial and durable weight loss is bariatric surgery. We refer readers to prior work for a summary on the Rouen-Y gastric bypass (RYGB) and sleeve gastrectomy (SG) procedure itself [1, 2], as here we summarize studies relevant to bariatric surgery as a gastrointestinal procedure that promotes favorable changes in insulin sensitivity and β -cell function for glycemic control. Because preservation of pancreatic insulin secretion is a primary determinant of glucose tolerance, we also discuss the mechanisms by which surgery improves β -cell function, and present evidence for the role of gut metabolism in a weight loss-independent way. In particular, we pay attention to surgery-induced changes in insulin secretion that may be influenced by hormones, bile acids and gut microbiota as these represent novel mechanisms potentially governing the rise in pancreatic function.

EFFECT OF BARIATRIC SURGERY ON BLOOD GLUCOSE

Obesity is a strong risk factor for type 2 diabetes. Excess body fat contributes to diabetes development by inducing insulin resistance and inflammation, which in turn, exacerbate β -cell function [3-5]. The notion that bariatric surgery “cures” diabetes has been recognized for over 20 years. In fact, Pories and colleagues [6] demonstrated in 141 patients with type 2 diabetes or impaired glucose tolerance that all but 2 individuals had normalized glucose tolerance within 10 days after RYGB. At 7.6 years after surgery, 83% of the patients with diabetes were off their anti-diabetic drugs, and 99% of those with impaired glucose tolerance were normoglycemic with a normal fasting glucose and HbA1c [7]. In the Swedish Obesity Study, at 2 years post-surgery with an average weight loss of nearly 28 kg, 72% of patients had complete resolution of type 2 diabetes compared with 21% of controls [8]. Many of these patients had been able to stop taking oral hypoglycemic drugs or insulin, which is in contrast to the control group who had an increased need for these agents. These results are similar to those of Scopinaro and colleagues [9, 10] who reported long-term follow up data on 312 patients with type 2 diabetes undergoing biliopancreatic diversion surgery. Their results indicated that 99% of patients achieved normal glucose concentrations by 1 year after surgery. At 10 years after surgery, 98% of the patients were still in complete remission of diabetes (i.e., normal blood glucose without anti-diabetic medication use). However, not all surgical approaches induce comparable glycemic benefit. Diabetes resolution was observed in approximately 98% of patients who underwent biliopancreatic diversion (with or without duodenal switch), 84% who underwent RYGB, 72% who underwent vertical banded gastroplasty surgery and 48% who underwent adjustable gastric banding [11]. In addition, it is also worth considering that more recent guidelines for diabetes remission have been

established, and current work suggests that approximately 50-70% of individuals undergoing RYGB or SG may not meet remission criteria at 5 years post-operation [12]. This would suggest that biological factors, such as weight regain or insulin resistance, may contribute diabetes relapse. Indeed, resolution of type 2 diabetes is likely to occur in those with the shortest duration of diabetes (<5 years) or milder forms of diabetes (diet-controlled), lower central obesity, and/or the greatest weight loss after surgery [13]. Conversely, patients that do not resolve diabetes post-surgery are usually older or have a more prolonged surgical disease course [7, 14, 15]. Thus, further work understanding how to optimize diabetes remission rates are needed following surgery. Nevertheless, the majority of these observational studies have been supported by randomized control trials (RCTs) in obese cohorts with type 2 diabetes [16-18]. For instance, the Surgical Treatment and Medications Potentially Eradicate Diabetes Efficiently (STAMPEDE) trial recently demonstrated the effects of bariatric surgery on controlling glycaemia in obese individuals with type 2 diabetes. In the STAMPEDE trial, Schauer and colleagues [19] compared the effects of RYGB and SG vs. intensive medical therapy in 150 obese patients with uncontrolled type 2 diabetes at 1 year post-operation. People were randomly assigned to surgical or medical therapy groups, and the primary endpoint was a HbA1c < 6.0%. The results indicated that RYGB and SG each produced significant improvements in HbA1c in 42% and 37% of patients, respectively, meeting glycemic control criteria. Taken together, bariatric surgery appears to result in dramatic glycemic control and weight loss improvements in obese patients with type 2 diabetes.

LINKING GUT METABOLISM TO OBESITY RELATED DISEASE POST-SURGERY

Although weight loss is likely important for gains in insulin sensitivity and β -cell function following bariatric surgery [20], restrictive procedures do not induce comparable diabetes resolution rates as compared to biliopancreatic diversion or RYGB. Moreover, despite malabsorption explaining to some extent reductions in reactive oxygen species and inflammation derived from excess glucose and lipid digestion in obese individuals, nutrient malabsorption does not occur after standard RYGB [21], implying that additional factors likely drive the improvements in glycemic control post bariatric surgery [22]. Altered gut metabolism is currently the leading candidate as the major mechanism following bariatric surgery explaining improved weight regulation and decreased type 2 diabetes and cardiovascular disease risk.

Rubino and colleagues have hypothesized that overstimulation of the gastrointestinal tract by overeating leads to metabolic disturbances that promote blood glucose elevations, whereas restricting food contact with the intestine improves these conditions [20]. A possible mean for improving insulin sensitivity and/or β -cell function is related to the secretion of various hormones released by the gut in response to the re-routing of food intake [23]. Surgical exclusion of the duodenum in the RYGB procedure and exclusion of the duodenum and jejunum in biliopancreatic diversion result in altered sites – or at least altered relative distribution – of carbohydrate and fat absorption. This in turn has been related to increased anorectic hormones that induce satiety (e.g., glucagon-like polypeptide 1 (GLP-1), polypeptide tyrosine-tyrosine (PYY), oxyntomodulin (OXM)) and decreased levels of the

orexigenic hormone ghrelin that promote hunger. Based on these observations, the “hindgut,” “midgut,” and “foregut” hypotheses have been raised. The hindgut hypothesis suggests that diabetes control is due to accelerated delivery of nutrients to the distal intestine, which augments an insulinotropic signal (e.g., GLP-1) that improves glucose homeostasis via enhanced insulin action [24]. Indeed, augmented GLP-1 secretion increases the insulin response to nutrient intake, and at least in animal models, induces β -cell proliferation [25], which together reduces blood glucose levels. In addition to a rapid delivery of nutrients to the distal intestine for GLP-1 secretion, the “midgut” hypothesis suggests that nutrient delivery to the distal intestine increases intestinal gluconeogenesis and activates a hepato-portal sensor that leads to neural signal for reduced food intake and lower hepatic glucose output (26). In contrast, the “foregut hypothesis,” suggests that nutrient interactions in the duodenum and proximal jejunum are diabetogenic and, hence, bypassing the duodenum alleviates this intestinal factor that induces insulin resistance and β -cell dysfunction [27, 28]. However, this later hypothesis has been controversial since the diabetic intestinal factor has not been identified and SG, which does not bypass the duodenum, improves glycemic control. It is important to note that although the “hindgut,” “midgut,” and “foregut” hypotheses are often explained in terms of hormonal changes, they are not exclusive of altered nutrient flow that affects neural signaling. Interestingly, patients following surgery often report a reduction in snack numbers and/or portion size as well as food preference. In fact, these individuals often have reduced preference for sweet and fat tasting foods [29]. In addition, although the gut hypotheses are often presented as mutually exclusive theories, no data actually exist excluding portions of the upper or lower intestine. Moreover, the exact molecular mechanism underlying the improvement in metabolism following RYGB is unknown, and it is likely that as a number of gut hormones and neural signals produced at various sites of the gastrointestinal tract elicit unique mechanisms of action. Indeed, RYGB was reported to enhance intestinal glucose uptake and utilization, leading to overall improvements in systemic glucose control [30].

GUT HORMONES POST-SURGERY: ROLE ON β -CELL FUNCTION

The enteroendocrine cells of gastrointestinal tract are comprised of cells that secrete hormonal factors that modulate not only food intake, but also the upregulation of insulin synthesis and secretion. For instance, L cells are located throughout the small intestine and colon, but are found in highest density within the lower portion of the small intestine. These L-cells are responsible for secreting GLP-1, OXM, and PYY. The release of these hormones, are well characterized, and considered major factors related to β -cell function. LaFerrere and colleagues (31) reported increased post-prandial levels of GLP-1 within 4 weeks following RYGB, whereas levels of GLP-1 did not rise with comparable weight loss induced by diet. These findings are consistent with data in patients with type 2 diabetes at 1 year following RYGB in which elevated GLP-1 was significantly associated with insulin action and weight loss [32]. In fact, enhanced β -cell glucose sensitivity (i.e., the relationship between circulating glucose and insulin secretion rates) increase independent of weight loss following RYGB in adults with and without type 2 diabetes [33], although β -cell glucose sensitivity is not observed following gastric band surgery despite comparable weight loss to that of RYGB

[34]. Bojsen-Moller and colleagues expanded on this prior work and characterized the longitudinal assessment of insulin secretion and multi-organ sensitivity at 1 week, 3 months and 1 year following RYGB in obese adults with and without type 2 diabetes [35]. Interestingly, at 1 week fasting glucose had significantly declined in patients with type 2 diabetes and this change in glycemia corresponded with improvements in hepatic glucose production since tests of skeletal muscle glucose disposal via the euglycemic clamp, free fatty acid suppression (measure of adipose insulin sensitivity), and pancreatic insulin secretion assessed by intravenous glucose tolerance tests revealed no change. However, at 3 months, while the improvement in the disposition index (i.e., insulin secretion $\times$ insulin sensitivity) indicated that insulin sensitivity is a key driver of systemic glucose control, insulin secretion in response to oral glucose was improved in people with type 2 diabetes and directly associated with GLP-1. These latter results highlight that the gastrointestinal tract per se plays a key role in the amelioration of type 2 diabetes. This notion is strengthened by evidence of the GLP-1 receptor inhibitor exendin₉₋₃₉ nearly eliminating the improved β -cell insulin secretion response to bariatric surgery [36]. In line with these observations, more recent work reports that SG produce similar rises in GLP-1 to RYGB surgery at 1 year in both obese non-diabetic and diabetic individuals [33, 37]. These findings are intriguing given that increased exposure of nutrients to the distal part of the intestine is a leading hypothesis for robust increases in GLP-1 post-RYGB surgery. It remains possible that SG accelerates gastric emptying compared to pre-surgery, and this contributes to greater nutrient exposure. Alternatively, other factors in the proximal region of the intestine may play a role. Indeed, it has been reported that both RYGB and SG surgery also increase GLP-1 and insulin secretion compared to intensive medical therapy 2 years post-surgery, although RYGB may provide some additional benefit [38]. However, unlike oral glucose ingestion, use of the intravenous glucose tolerance test suggests that insulin secretion does not change post-bariatric surgery despite improvements in glycemic control [35]. Subsequently, the collective work in the literature suggests that the intestinal system is a key mechanism increasing insulin secretion, and that improvements in post-prandial hyperglycemia occur in conjunction with the disposition index mainly due to rises in insulin sensitivity. Therefore, factors other than GLP-1 alone likely play a role in improved glucose homeostasis after bariatric surgery.

GIP is secreted in the K-cells located mainly in the duodenum and proximal jejunum and released in response to nutrients (mainly lipid). Unlike, GLP-1, GIP is more involved in lipid metabolism (storage) and is thus thought to play a more direct role in the pathogenesis of obesity. While some report similar improvements in GIP between RYGB and SG surgery [39], others have documented GIP levels to be unchanged following surgery [38]. Subsequently, the effect of bariatric surgery on GIP is more controversial than the findings of GLP-1, and the role of GIP is less clear on the regulation of lower fat mass and/or insulin secretion following surgery. Nevertheless, like GLP-1, PYY and OXM are co-secreted by the L-cells of the distal small intestine and are responsible for reducing hunger, decreasing food intake and delaying gastric emptying after meals. Several studies have documented increases in postprandial PYY and GLP-1 after RYGB [40-42], with some also reporting enhanced OXM [43]. Although no published study to date has determined the role of SG on OXM, SG has been reported to elevate PYY and GLP-1 [33, 37, 44]. Ghrelin is a gastric hormone produced primarily in the stomach with secondary secretion emanating from the proximal small intestine, and ghrelin has been documented to play a role in both appetite stimulation as well as impairing insulin sensitivity and reducing glucose-stimulated insulin secretion [45].

Ghrelin suppression is usually improved following RYGB or SG, suggesting that suppression of hunger signals helps sustain weight loss. However, it is worth considering that these surgery types may exert different mechanisms to lower ghrelin. Indeed, prior work by Malin and colleagues suggested that RYGB is effective at suppressing post-prandial ghrelin levels, while SG surgery primarily lowers fasting ghrelin [46]. This phenomenon of ghrelin suppression vs. lower fasting ghrelin may contribute to changes in GLP-1 and β -cell function, although further work is needed. In either case, both surgery types appear effective at reducing ghrelin levels, and this likely contributes to some extent on the beneficial weight regulation and insulin secretion changes post-surgery.

ROLE OF BILE ACIDS ON β -CELL FUNCTION

Bile acids are traditionally known for their role in micelle formation and processing/digestion of dietary fat. However, it is now clear that bile acids contribute to energy metabolism and glucose regulation before and after bariatric surgery. Patti and colleagues demonstrated that total plasma bile acids were significantly elevated compared with weight matched controls in post-RYGB patients [47]. Interestingly, Pournaras and colleagues [48] showed that fasting total serum bile acids are elevated within days following RYGB, but not LAGB, suggesting that bile acids may contribute to weight-independent improvements in glucose homeostasis. Indeed, fasting total bile acids are inversely correlated with post-prandial glucose and positively correlated with peak GLP-1 levels [49] and 2-hour blood glucose levels [47]. In line with these observations, bile acids are known to act on TGR5 receptors located on enteroendocrine cells and promote the secretion of GLP-1 release [50], which may contribute to satiety and β -cell insulin secretion. In fact, farnesoid X receptor (FXR) in pancreatic β -cells may directly respond to the rise in bile acids, thereby increasing insulin release [51]. However, not all studies support the theory that bile acids play an important role in GLP-1 induced pancreatic β -cell function. In fact, recent work showed that bile acids do not rise within the first week post-RYGB and SG despite improved glycemic control [52, 53]. These latter results suggest that while bile acids may contribute to improved gut hormone secretion over longer periods of time, bile acids may not explain the early effects of bariatric surgery on glucose tolerance and GLP-1. Thus, further work is required to understand independent and dependent mechanisms by which bile acids affect β -cell function post-bariatric surgery.

RELATIONSHIP OF GUT MICROBIOTA AND OBESITY RELATED DISEASE RISK

The gut microbiome has emerged as an important regulator of obesity, metabolism and inflammation. In human intestine, approximately 400 bacterial species are present and together resemble a multicellular organ that has evolved to provide complex nutrient signaling and metabolic functions [54]. The vast majority of these microorganisms belong to 3 main groups: *Firmicutes*, *Bacteroidetes*, and *Actinobacteria* (comprising of 95% of total intestinal bacteria) and reside in the distal portions of the intestine. The gut microbiome is a

dynamic organ that changes in response to the environment. In animals provided a high-fat diet, the gut microbiota resulted in increased levels of *Firmicutes* prior to the development of obesity [55]. This renders the microbiota to be more obesogenic and may result in increased energy harvest from the diet. In line with this observation, Ley and colleagues demonstrated that food restriction, not macronutrient content per se (low-carbohydrate vs. low-fat), was linked to decreased levels of *Firmicutes* and elevated levels of *Bacteroidetes* [56], suggesting that nutrient overload is important for gut bacteria modifications. For instance, this altered gut microbiome has been associated with intestinal inflammation and systemic insulin resistance [57]. Further evidence for a role of gut microbiome on metabolic health is evident from germ-free rodents, which are protected from developing diet-induced obesity. In fact, germ-free mice have lower adiposity and have higher food consumption when compared with control mice. But when germ-free mice are colonized with cecal content from control mice, weight is rapidly gained and food consumption decreases, suggesting that gut microbiome regulates fat mass and energy store [58]. Further, genetically identical mice fed high-fat diets differed in their metabolic phenotype due to differences in gut microbiota composition [54], indicating that the cause of metabolic disease may be due to a complex interaction of environmental factors as well as gut microbiota profiles. In either event, germ-free mice have reduced expression of CD36 and SGLT-1, which are important for fatty acid and glucose transport in the intestine [59]. Together, these data highlight gut bacteria as important modulators of nutrient absorption, and suggest that two mechanisms are likely involved in explaining the link between obesity and gut microbiome. First, increased capacity to process otherwise indigestible polysaccharides, leading to subsequent rises in nutrients, and second, increased gene expression promoting fat storage in adipose tissue [58]. Thus, a current working hypothesis is that obese animals are better able to extract energy from dietary intake and store those calories as fat. Indeed, obese humans have fewer calories from the diet in feces [60].

EFFECT OF BARIATRIC SURGERY ON GUT MICROBIOTA

Bariatric surgery changes gut microbiota to reflect more of a lean phenotype. Zhang and colleagues [61] showed that microbiota functional differences occurred in obese individuals post-RYGB surgery. In fact, RYGB markedly altered *Gammaproteobacteria* (member of *Enterobacteriaceae*), decreased *Firmicutes*, and lowered methanogens (key for energy harvest). Similarly, Furet and colleagues [62] reported that gut microbiota adapted to RYGB surgery by increasing the *Bacteroides/Prevotella* ratio, which was correlated with reduced body fat. Moreover, *Escherichia coli* species also increased in individuals undergoing RYGB, and this change was significantly correlated with fat mass and leptin independent of caloric intake restriction. Changes in adipose tissue mass is strongly linked to systemic inflammation, and consistent with weight loss following RYGB, the rise in *Faecalibacterium prausnitzii* species in people with type 2 diabetes was related to lower inflammation (hs-CRP and IL-6). Together, these findings strengthen the view that obesity and gut microbiota are intimately involved in the regulation of metabolic health. In fact, Kong and colleagues [63] demonstrated that RYGB increased gut microbiota richness, and this change in gut microbiota was directly correlated with genes encoding white adipose tissue mass, metabolism and inflammation. Interestingly, approximately 50% of these relationships were independent of

caloric intake, suggesting that RYGB uniquely alters gut metabolism in favor of weight reduction maintenance. Although distal portions of the small intestine contribute to the majority of nutrient absorption and gut microbiome in humans, the upper portions include gut bacteria that have metabolic function. Indeed, when microbiota from lean individuals are administered into the duodenum of humans with metabolic syndrome, insulin resistance declines independent of weight loss [64], suggesting that exclusion of the duodenum contributes to the regulation of glucose metabolism.

The cause for this altered gut flora milieu is presently an area of intense research, but several proposed mechanisms are currently being investigated. First, the surgical induced restriction in food intake and/or change in food preference, including lower sugary foods and dietary fat, may explain modifications in the gut microbiome composition because of the smaller stomach size and shorter intestinal length [58]. Next, by diverting nutrients away from the proximal intestine, gut microbiota are exposed to more rapid food delivery and adapt accordingly. For instance, intestinal cells are exposed to more oxygen than usual due to the shorter intestinal lengths and facultative anaerobes occurs. Lastly, from an anatomical perspective, pH levels rise after RYGB surgery in the stomach and upper intestine. Although a $\text{pH} < 4$ is potentially “deadly” for many microorganisms, some reports suggest that pH modification affects the overall gut microbiota composition. Further, modification of acid secretion following RYGB not only lowers distal small intestine pH and influences the production of deconjugated primary bile acids, but also increases acidification in the distal small intestine thereby increasing secondary bile acid levels via gut bacteria. Indeed, elevated secondary bile acid levels are reported to decrease hepatic fatty acid uptake, which may contribute to improvements in hepatic triglyceride metabolism and hepatic steatosis [80]. Alterations in gut microbiome in the colon have also been linked to lower pH, and this altered gut bacteria favors the rise in short-chain fatty acid production, which may have lipid metabolism regulatory effects [65]. Taken together, these findings following RYGB surgery support the gut microbiome as being a key physiologic player involved in fostering nutrient sensing for both weight regulation and glucose homeostasis [63].

EFFECT OF GUT DERIVED INFLAMMATORY METABOLITES ON METABOLIC HEALTH

Low-grade inflammation in humans is a common co-morbidity of type 2 diabetes and cardiovascular disease. Locally, the gut microbiome is directly linked to intestinal inflammation via changes in bacterial fragments and/or metabolites known to increase innate immune system responses. Interestingly, these bacterial components and metabolites have implicated the gut microbiome as a key factor in the development of obesity and metabolic disease [66]. The innate immune system has the capacity to sense various bacterial components (e.g., via toll-like receptors (TLRs)) and while several gut derived materials have been documented to play a role in chronic disease, endoxemia by means of lipopolysaccharides (LPS) as well as short chain fatty acids (SFCAs) have received much recent attention as it specifically pertains to inflammatory related mechanisms of glucose regulation.

ROLE OF LIPOPOLYSACCARIDES

LPS originating from Gram-negative bacteria in the gut induces low-grade inflammation and insulin resistance, thereby contributing to disturbances in energy metabolism that promote metabolic disease. LPS is sensed by TLR4, and is elevated in the circulation following high fat diets via a “leaky gut” phenomena (or chylomicron transport mechanism) [67]. This may be of particular relevance for humans, as obesity is associated with elevated circulating LPS levels compared with healthy controls [68]. Human work also supports the LPS linkage to hyperglycemia, as treatment with insulin-sensitizing agents in patients with type 2 diabetes lowered LPS in line with greater rises in insulin action [69]. Further, elevated LPS in type 1 diabetic and kidney vascular disease were highly associated with serum triglycerides, diastolic blood pressure and inflammation markers (e.g., MCP-1) [70], suggesting that metabolic LPS is linked to cardiovascular disease. Given that bariatric surgery alters the gut microbiome composition, it would seem reasonable to suspect changes in LPS. The limited evidence suggests that not only does bariatric surgery reduce LPS, but also this reduction in LPS is directly linked to lower adipose mass and improved HbA1c levels [68]. Taken together, it appears LPS is related to obesity-induced disease risk, but additional work is required to determine if LPS has direct roles on insulin sensitivity and/or pancreatic function.

ROLE OF SHORT CHAIN FATTY ACIDS

SCFAs on the other hand are produced in the colon by gut microbes that ferment non-digestible polysaccharides (e.g., inulin) [71]. The rise in SCFA (i.e., acetate, butyrate, and propionate) levels are important for weight regulation as they are implicated in satiety and decreased food intake, although SCFAs may act as substrate for lipogenesis. As mentioned previously, improved β -cell function following bariatric surgery is in part related to elevated GLP-1 as well as lower ghrelin. The effects of bariatric surgery on gut hormones and gut microbiome would suggest that the changes in SCFA could contribute to the overall regulation of insulin secretion. Interestingly, SCFA have been shown to influence gut peptides, appetite and energy expenditure [67]. Although studies in humans are limited, Arora and colleagues [72] suggested that propionate may reduce appetite. In addition to the effects on gut peptides, butyrate and propionate may increase leptin secretion from adipocytes [73]. This later mechanism may provide an alternative mechanism by which the gut directly communicates with adipose tissue to regulate body weight and feeding behavior. While SCFAs may play important roles in body weight regulation through increases in total energy expenditure [74], SCFAs also act on GPR43 receptors in L cells of the small intestine. Since L cells are also responsible for GLP-1 secretion, it is reasonable that SCFA may influence insulin secretion [75]. Recent work by McNeelis and colleagues [76] supports this hypothesis and identified GPR43 as a modulator of microbiota-pancreatic cross-talk. Interestingly, high fat diet feeding increased the expression of GPR43 and serum levels of acetate. Knockout mice of the GPR43 receptor developed glucose intolerance in part due to inadequate insulin secretion. Treatment of islets with the GPR43 receptor agonist, however, demonstrated that insulin secretion could be restored, thereby providing evidence that activation of GPR43 by

SCFA may initiate insulin responses post-feeding. Overall, these data highlight SCFA as an important factor that reduces appetite and/or increases energy metabolism to promote insulin secretion and action following bariatric surgery.

ROLE OF TRIMETHYLAMINE-N-OXIDE

Gut microbiota release choline from dietary phosphatidylcholine where it gets metabolized to trimethylamine (TMA). TMA is transported to the liver via the portal vein and is oxidized to trimethylamine-N-oxide (TMAO). Elevated levels of plasma TMAO, choline, and betaine have dose-dependent associations with the presence of cardiovascular disease independent of conventional risk factors (e.g., blood pressure, triglycerides, etc.) and medication use [77]. Rats fed high choline diets or TMAO diets develop elevated circulating TMAO levels and greater aortic root atherosclerotic plaque without alterations in plasma glucose or blood lipids. Although obesity may influence circulating TMAO levels, dietary manipulation appears important for modulating TMAO, such that high fat and increased meat consumption lead to greater elevated TMAO compared with low fat and vegetarian style meals. Gut microbiota production of TMAO following bariatric surgery is sparse, as some urinary data suggest that TMA is elevated in rodents following bariatric surgery [78]. Increased TMAO levels have also been demonstrated in humans with and without diabetes following bariatric surgery, although lifestyle modification had no effect [79]. While a rise in TMAO post-surgery would be unexpected given the relationship to cardiovascular disease, future prospective work is needed to determine the impact TMAO has on metabolic health. Additional work is also warranted to determine if gut microbiota therapies influence TMAO since this metabolite appears to be independently associated with cardiovascular disease risk [80].

IMPLICATIONS AND CONCLUSION

Bariatric surgery is a proven treatment option for weight loss and glycemic control. However, much of the metabolic benefit derived from surgery occurs within days following the operation. The resulting weight loss from bariatric surgery is persistent in most patients, and this durability in weight loss is considered an underlying mechanism responsible for the majority of glycemic control benefit and cardiovascular disease risk reduction. However, it is clear that gut metabolism has distinct effects on not only appetite, but also on insulin sensitivity, β -cell function, and blood glucose. Specifically, GLP-1, PYY and ghrelin not only impacts satiety but also modulates whole body insulin secretion and sensitivity. In addition to alterations of the stomach, proximal to distal small intestine re-routing of nutrient delivery to the jejunum may contribute to increased bile acids, intestinal remodeling, and changes in the gut microbiome that collectively contribute to improved glucose and insulin metabolism. In fact, identification of novel gut derived metabolites related to inflammation suggests that the gastrointestinal tract “cross-talks” with several tissues (e.g., skeletal muscle, liver, adipose, pancreas) to impact blood glucose regulation. Thus, additional work is required to determine the exact mechanism by which gastrointestinal, neuronal, and endocrine systems contribute to

diabetes remission and β -cell function. Taken together, the interaction between the gastrointestinal tract and obesity related metabolic improvements seen following bariatric surgery warrant referral to chronic disease, such as type 2 diabetes, as a “gastrointestinal related disease.” Further understanding of mechanisms related to gut metabolism following bariatric surgery, with or without lifestyle modification, will likely promote innovative medical strategies that improve rates of obesity, type 2 diabetes and cardiovascular resolution.

Chapter 146

CT SCAN AND 3D APPLICATIONS FOR HIP SURGERY

T. Robba*, D. Molino, D. Martorano and A. Borre'

Radiology Department, Città della Salute e della Scienza di Torino –
C.T.O. Hospital, Torino, Italy

ABSTRACT

Since its introduction in the seventies, Computed Tomography has evolved into an essential diagnostic imaging tool for an ever-increasing variety of clinical applications. CT was the first technology to combine a computer with a medical imaging machine, the first to display X-ray images as cross sections and the modality that marked the beginning of a new era in digital imaging. It has quickly become the choice examination in the diagnosis of traumatic and musculoskeletal lesions. Indeed, in hip diseases, anthropometric measurements of acetabular geometry and orientation determine the decision-making process regarding surgical treatment and also affect outcome. Improvements in MPR and 3D imaging have given clinicians the opportunity to find practical tools for qualitative and quantitative evaluation of acetabular pathology. It is now also used in interventional imaging (injection guidance, bone and soft tissue biopsies, vertebroplasty, etc.). CT has helped with surgical decision in fractures (fractured neck of femur for example is a serious consequence of falls in the elderly, and is associated with high morbidity and mortality); it is also important in the assessment of avascular necrosis. CT defines the entire surface of the femoral head better than axial radiographs in the osteoarthritis, helping in the choice of total hip replacement over osteotomy and allowing more precise preoperative planning. CT allows for the evaluation of the femoroacetabular impingement parameters independently from the position of the patient and the pelvic tilt and, for this reason, should be used in pelvic pre-operative evaluation. CT is also important in total hip replacement because it can depict peri-implant fluid and soft-tissue masses that may be completely hidden on radiography.

Keywords: CT scan, hip surgery, 3d reconstruction

1. INTRODUCTION

1.1. Principles of Physics and Technical Considerations

Since its introduction in the seventies, Computed Tomography has evolved into an essential diagnostic imaging tool for an ever-increasing variety of clinical applications. The word tomography derives from the Greek word “*tomos*” meaning section, so the process of tomography involves the generation of narrow sections through an object. CT was the first technology to combine a computer with a medical imaging machine, the first to display X-ray images as cross sections and the modality that marked the beginning of a new era in digital imaging. Between 1957 and 1963, a South African physicist, A. Cormick, independently developed a method of calculating radiation absorption distributions in the human body, based on transmission measurements. He postulated that CT would be able to display very small differences in the absorption through the body, but never applied his research. In the early 1970s, CT scanning was conceived, yet again, by William Oldendorf and developed by Godfrey Hounsfield (Nobel prize winner in 1979 for Physiology and Medicine). CT was introduced into clinical practice in 1971 with a scan of a cystic frontal lobe tumour in a patient at Atkinson Morley Hospital in Wimbledon (United Kingdom). After this, CT was immediately welcomed by the medical community and has often been referred to as the most important invention in radiological diagnosis, since the discovery of X-rays [1].

A CT system consists of an X-ray source, a sliding table, an X-ray detector and a data processing unit for computation, visualisation and data analysis of measurement results. CT creates cross-section images by projecting a beam of emitted photons through one plane of an object from defined angle positions performing one revolution.

X-rays are electromagnetic waves with a wavelength smaller than approximately 10 nm. The energy of each photon is proportional to its frequency and the X-ray energy is usually expressed in eV ($1\text{eV} = 1.602 \times 10^{-19}\text{J}$). X-rays are produced when an accelerated beam of electrons is delayed by a metal object (target material, usually corresponding to the anode), with emission of X-ray photons. An X-ray source consists of a hot cathode (tungsten filament) and an anode inside a vacuum tube, between which an electrical potential is applied. Electrons ejected from the cathode surface are accelerated towards the anode. When these electrons impinge on the target, they interact with these atoms and transfer their kinetic energy to the anode. These interactions occur within a very small penetration depth into the target. As they occur, the electrons slow down and finally almost come to rest, at which time they can be conducted through the anode and out into the associated electronic circuit. The electron interacts with either the orbital electrons or the nuclei of the metal atoms. The interactions result in a conversion of kinetic energy into thermal energy and electromagnetic energy in the form of X-rays.

As the X-rays (emitted photons) pass through the patient, some of them are absorbed, some are scattered and some are transmitted. The process of X-ray intensity reduction, involving only X-rays that are scattered or absorbed, is called attenuation. X-rays that are attenuated due to interactions with the tissues do not reach the X-ray detector. Photons transmitted through the patient at each angle are collected on the detector, measured as a local attenuation coefficient in “Hounsfield units” and coded in grey value. Each image (“slice”) of the body scanned is divided in a matrix of voxels (volume picture element), whilst the

corresponding CT image of the slice is divided into pixels (picture element): a voxel of CT image corresponds to each voxel of the slice.

For each voxel, the attenuation coefficient is calculated and coded in a grey value attributed to the corresponding pixel. In other words, each voxel is assigned with a grey value of the corresponding pixel, representing a local X-ray absorption density. The quality of the image depends on several parameters that have to be set before the CT scan is performed, bearing in mind that the absorbed dose depends on them. These parameters refer to the energy of the X-ray source (mAs, KV), the slice thickness, the dimensions of the voxel and the depth of matrix (256x256, 512x512, etc.), the dimension of the FOV (field of view: 40x40 cm, 24x24 cm), depending on the anatomic district and other more in depth parameters.

In the evolution of CT, further types of scanners have followed. The *first two generations* of CT scanners (or single-slice CT scanners) did not provide volumetric studies and were superseded in the late 1970s by third- and fourth-generation scanners, which are still in use today as well as fifth-generation CT.

First-generation CT systems are characterised by a single X-ray source (pencil beam) directing across the object and a single detector. Both the source and the detector, translate simultaneously in a scan plane. This process is repeated for a given number of angular rotations. The most important disadvantage of first-generation CT was a longer scanning time.

Second-generation CT systems use the same translate/rotate scan geometry as the first generation. The difference here is that a pencil beam is replaced by a fan beam and a single detector by multiple detectors, so that a series of views can be acquired during each translation, which leads to correspondingly shorter scanning times. So, objects of wide range sizes can be easily scanned with the second-generation scanners.

Third-generation scanners, tube and detector arrays rotate synchronously around the patient. The detector array covers the full width of the fan beam.

The introduction of spiral CT in the early 1990s (*third-generation*) constituted a fundamental evolutionary step in the development and ongoing refinement of CT imaging techniques. For the first time, volume data could be acquired without misreporting of anatomic detail.

Fourth-generation CT systems also use a rotate-only scan motion. The detector elements cover a full circle around the scanner opening and remain stationary during the scan, while only the x-ray tube rotates around the patient. The number of views is equal to the number of detectors. These scanners are more susceptible to scattered radiation.

Fifth-generation CT systems are different from the previous systems, in that there is no mechanical motion involved. The scanner uses a circular array of X-ray sources, which are electronically switched on and off. The sources project onto a curved fluorescent screen, so that when an X-ray source is switched on, a large volume of the part is imaged simultaneously, providing projection data for a cone beam of rays diverging from the source. Here, a series of two-dimensional projections of a three-dimensional object is collected.

The ability to acquire volume data also paved the way for the development of three-dimensional (3D) image processing techniques such as multiplanar reformation (MPR), maximum intensity projection, surface-shaded display, and volume-rendering techniques, which have become a vital component of medical imaging today.

1.2. Post-Processing Reconstruction

The creation of new and customised visual representations by applying mathematical algorithms to the original data is called a reconstruction technique. Many techniques have been developed to post-process CT volumetric data. The simplest techniques extract one single parameter of the volumetric data and produce two-dimensional reconstructions highlighting a desired structure. These reconstructions are two-dimensional MPRs (multiplanar reconstructions) and can also be performed on curved planes (along vessels, lordosis or kyphosis of the spine, etc.). They generally provide superior anatomic detail, whereas surgeons tend to prefer three-dimensional images for surgical planning. Multi-planar reconstruction is the reformatting of data, typically along the sagittal and coronal plane, although any off-axis slice can also be obtained.

1.3. 3D Reconstruction

When the acquisition process of the scanned object is completed, reconstruction algorithms are used to reconstruct the 3D volume [2]. These reconstructed 3D images are made of voxels. There are several 3D post-processing techniques available. Volume rendering reconstruction (VR) takes the entire volume of data, calculates the contributions of each voxel (volume pixel) along a line from the viewer's eye through the data set, and displays the resulting composite for each pixel of the display. Threshold value is a critical parameter in CT and is used for accurate image segmentation and surface data determination, which influence the resulting reconstructed geometry of the scanned object. Threshold converts a grey value image into a binary one. The resulting image then comprises two sets: one represents the background (e.g., black), the other the object (e.g., white). In principal, a threshold determines where the boundaries lie between the object and the air, so that a surface can be assigned to the scanned object.

Except for cases with secondary vascular imaging, the key reconstruction algorithms used in pelvic bone imaging are shaded-surface display and volume rendering. The correct acquisition and reconstruction of axial image data is the base for a multi-planar two-dimensional reformatted image or a 3D CT image. The 3D rendering software algorithms attempt to display 3D spatial relationships in a two-dimensional image [3]. Both shaded surface rendering and volume rendering have been advocated as reconstruction algorithms for 3D musculoskeletal imaging, but certain advantages of volume rendering make it our preferred algorithm for all 3D musculoskeletal imaging applications. Volume algorithms show 3D relationships with varying degrees of success depending on the degree of surface shading and opacity. Volume-rendered images may be viewed in any plane or projection and in a range of opacities, from transparent to opaque.

1.4. Dose and Noise

Noise is caused by the variation in attenuation coefficients between individual voxels. In CT, we are measuring the attenuation coefficients of the individual tissue voxels. If we have two voxels with identical tissue, we would expect to measure identical attenuation coefficient

values and, when these are translated into CT numbers, we would expect to obtain similar numbers. In reality, we do not due to the noise, which is the random variation of density and which can be quantified. The amount of this variation can be evaluated by determining the standard deviation, which is the easiest and an excellent way of quantifying the amount of noise in CT images. All CT systems have the software capability of defining a region of interest (ROI) and measuring and calculating the standard deviation of this ROI. To decrease noise, we must increase the number of X-ray photons absorbed in each voxel during the imaging process. The quantity of radiation photons in each voxel can be controlled in two ways: adjusting the size of the voxel or modifying the exposure. Obviously, a large voxel will intercept and absorb more photons than a small voxel and will result in decreased noise in the image. The other way of controlling the quantity of absorbed radiation photons per voxel is by increasing the total radiation imparted to the patient. This is controlled through the number of photons emitted per second by the X-ray source, which depends on the current intensity applied on the cathodic tube (mAsecond or mAs). By increasing the milliampere seconds, we deposit more photons in each voxel of tissue, which results in less statistical variation (less standard deviation), therefore, less noise in the image. We must bear in mind that increasing the milliampere seconds leads to an increased absorbed dose. This is why many technological innovations have tended to reduce the dose delivered over the last few years. The best example is the recent appearance of iterative reconstructions that reduce the dose by half with an equivalent image quality [4]. With these technological innovations and better control of the optimisation of the acquisition parameters, it is now possible to obtain CT imaging with a dose almost equal that of the standard X-ray assessment while the diagnostic performance of CT is much higher than that of X-rays. Moreover, one of the benefits of iterative reconstructions is the possibility of reducing the artefacts, in particular, the beam hardening artefacts. This is of particular interest in the analysis of the soft tissue and bone structures in contact with osteosynthesis material [5].

1.5. Contrast Media in CT: CT and Perfusion-CT

Intravenous contrast is used in CT to help highlight blood vessels and to enhance the tissue structure of various organs. Contrast-enhanced CT is used to find pathologies by enhancing the contrast between a lesion and normal surrounding structures. Therefore, it is important to know in which phase a CT should be performed, depending on the pathology that you are looking for.

The major families of contrast agents are ionic and nonionic. Contrast agents can be further classified as high or low osmolality, based on the iodine concentration. Most centres use nonionic contrast agents (which are generally low osmolality) for IV contrast studies. The rate of major reactions (e.g., anaphylaxis, death) is the same for ionic and nonionic IV contrast agents - an estimated one in 170,000 administrations - but nonionic contrast agents have a lower rate of minor reactions. Approximately 5% to 12% of patients who receive high-osmolality contrast have adverse reactions, most of which are mild or moderate. Use of low-osmolality contrast has been associated with a reduction in adverse effects. Children have a lower incidence of reactions to IV contrast agents and most of these are mild (0.18% for low-osmolality agents).

The CT with contrast study comprises different phases:

- non-enhanced CT. Helpful in detecting calcifications, fat in tumours, fat-stranding as seen in inflammation such as diverticulitis, omental infarction, etc.
- early arterial phase - 15-20 sec. This is the phase when the contrast is still in the arteries and has not enhanced the organs and other soft tissues.
- late arterial phase - 35-40 sec. Sometimes also called “arterial phase” or “early venous portal phase”, as some enhancement of the portal vein can be seen. All structures that receive their blood supply from the arteries will show optimal enhancement.
- hepatic or late portal phase - 70-80 sec. Although hepatic phase is the most accurate term, most people use the term “late portal phase”. In this phase, the liver parenchyma enhances through blood supply by the portal vein and you should see the enhancement of the veins.
- nephrogenic phase - 100 sec. This is when all of the renal parenchyma, including the medulla, is enhanced.
- delayed phase - 6-10 minutes. Sometimes called “wash-out phase” or “equilibrium phase”. There is wash-out of contrast in all abdominal structures except for fibrotic tissue, since fibrotic tissue has a poor late wash-out and will become relatively dense compared to normal tissue.

The use of intravenous contrast material is not usually necessary for the pelvic bone study, but is usually used in combination with abdominal CT scans during initial high-energy blunt trauma evaluation. When pelvic CT scans are obtained alone for the detection of subtle fractures and displacements not appreciated on radiographs, intravenous contrast can be used to create vascular maps to rule out vascular injury. In pelvic trauma, if vascular injury is suspected, a spiral CT using CT angiographic technique would ideally be used. In this process, we can evaluate the lower abdominal aorta, iliac vessels and their branching as well as the bony pelvis in a single examination. Rapid-acquisition spiral CT allows the entire dataset to be acquired at the peak of contrast enhancement. In these cases, a delay of 30–40 in scanning is ideal. Three-dimensional images produced with maximum intensity projection or volume-rendering techniques require an optimal administration of contrast material if vascular images are to be generated. Injection rates are typically 2–4 ml/s.

The use of CT with contrast in the hip and musculoskeletal system is important in trauma to assess bleeding.

Perfusion CT was first described many years ago [6]. Like with dynamic examinations, the CT perfusion of musculoskeletal tumours is possible due to an improvement in the temporal resolution of multislice CT imaging and the development of multidetector CT. The study of perfusion by CT combines the advantages of perfusion imaging, providing data similar to that provided by the MRI but with better visualisation of bone invasion (periosteal reaction, cortical break, osteolysis), femoral necrosis and neovascularisation. The quantification of perfusion curves by CT is as easy as with MRI [7].

1.6. Dual Energy Computed Tomography

Dual energy CT is based on the acquisition of two superimposable images with two different kilovoltages. Based on these native images, it is possible to reconstruct a virtual image corresponding to any voltage of the X-ray tube [8]. Each manufacturer proposes dual energy acquisitions on their CT. However, the techniques used often differ. This accounts for differences in terms of performance and clinical applications between these techniques. Several applications of the dual energy CT in the osteoarticular domain are now clinically available although still in the assessment phase: improvement in tissue characterisation, bone subtraction, differentiation of bone and iodine contrast product or even reduction of metallic artefacts. The improvement in tissue characterisation was first used for the detection and characterisation of urate deposits in gout [9]. An initial study by Nicolaou et al. [10] demonstrated that the dual energy acquisition of all peripheral joints (elbows, wrists, hands, knees, ankles and feet) provides good sensitivity and good specificity in the detection of locations of tophaceous gout, while the total effective dose ranged from only 2 to 3 mSv. Another dual energy application is the possibility of obtaining reconstructions in bone subtraction. It is then possible to detect bone marrow oedema. Pache et al. [11] demonstrated that it was possible to detect post-traumatic bone marrow oedema in knee CT imaging, with an increase in irradiation of about 28% compared with a conventional CT. The dual energy bone CT may also become an alternative in case of contraindication for MRI or if this is unavailable. However, clinical studies are required to specify the role of this technique compared with MRI [12]. Finally, with a dose equivalent to that of a standard single energy acquisition, Bamberg et al. [13] demonstrated that the use of dual energy allowed for a reduction in prosthesis-related metallic artefacts.

2. CT IN MUSCULOSKELETAL RADIOLOGY

Since its introduction in the 1970s, computer tomography has played a major role in the diagnosis of many osteoarticular diseases. It has quickly become the choice examination in the diagnosis of traumatic and malformative lesions. Indeed, in hip diseases, anthropometric measurements of acetabular geometry and orientation determine the decision-making process regarding surgical treatment and also affect outcome. Improvements in 3D imaging have given clinicians the opportunity to find practical tools for qualitative and quantitative evaluation of acetabular pathology. It is now also used in interventional imaging (injection guidance, bone and soft tissue biopsies, vertebroplasty, etc.) [14]. However, the performance of CT is limited by the less contrast resolution for soft tissues compared with Magnetic Resonance Imaging (MRI) and, above all, CT is X-ray-related imaging. For all of these reasons, MRI has taken a preponderant role in musculoskeletal imaging. Nevertheless, in recent years, the speed of acquisition and spatial resolution with submillimetric isotropic acquisitions of CT have considerably improved and, as mentioned before, recent technological evolutions reduce the dose the patient is exposed to. As opposed to MRI, the other advantages of CT include its lower cost, improved availability, the possibility of use on postsurgical or unstable patients and the absence of contraindications related to prosthetic materials or pacemakers. Therefore, the scanner still plays an important role in osteoarticular disease [15].

3. CT OF THE HIP AND PELVIC ANATOMY

The osseous anatomy of the pelvis is a complex union of the sacrum and two hemipelvic bones, each derived from three smaller bones: the ilium, ischium and pubis. Each of these bones is of a variable thickness and they are spatially oriented at a different angle with respect to each other and to the different axes of the human body. The pelvis is firmly fixed at the sacroiliac joint and its moves as a unit. This means it is impossible to project, in traditional radiology, some areas free of overlying osseous structures. Thus, the deeper and more central structures such as the posterior iliac spines, the sacroiliac joints and most of the sacrum are particularly difficult to image. Overlying faecal matter and bowel gas further compromise conventional radiologic evaluation of the sacrum. Computed tomography overcomes these anatomical difficulties and graphically displays both the anatomic location and intraosseous extent of osteolytic lesion of the pelvis.

The hip is a ball socket joint with a complex origin of the socket, due to the contribution of three bones joined at the triradiate cartilage. These separate contributions to the acetabulum are seen in paediatric patients. At this age, it is apparent that the acetabular roof is contributed by the ilium, the small antero-medial portion by the pubic bone and the major postero-medial portion by the ischium. CT has been shown to have a role in solving selected problems related to congenital hip dislocation, trauma and infection.

In adults, CT scans of the hip have been useful due their display of cross-sectional anatomy. Computed Tomography shows that the acetabulum is not merely a socket, but rather a focal concavity supported at the apex of an arch derived from two substantial columns of bone. The posterior, or ileo-ischial, column is large and descends from the sciatic notch to the ischial tuberosity. The anterior, or ileopubic, column runs downwards, inwards and forwards from the iliac crest to the pubic symphysis. The periphery of the acetabulum narrows into a labrum that is complete except inferiorly, where it meets the acetabular fossa. The posterior acetabular rim is more substantial and extends further laterally than the anterior rim. The femoral head is seated centrally in the acetabulum, but may not be shown with an equal width of cartilage space around it. When supine and relaxed, the patient, assisted by gravity, permits the leg to rotate externally. This causes minimal subluxation of the femoral head so that the anterior joint space is slightly wider than the posterior.

4. CT IN HIP TRAUMA

Computed tomography of the hip has made its greatest contribution in the evaluation of hip fracture-dislocations. CT has few of the disadvantages of conventional radiography. Computer tomography is simple and accurate, whereas radiography now seems cumbersome and less accurate. Standard radiography requires moving the patient into various positions, which can be painful and there is always concern that further displacement may occur. When optimal radiographs are obtained, they still provide only two-dimensional information. Computed tomography is accomplished without moving the patient's leg or pelvis into various positions and provides three-dimensional information.

The fracture-dislocation pattern and the complications associated with each determine whether or not the specific injury will be treated or subjected to surgery. Computer

tomography has helped with this surgical decision. For a hip to do well following an acetabular fracture, there must be no major intra-articular fragments. The posterior acetabular labrum must be stable and the fragments must be anatomically reduced so that there is minimal incongruity between the femur and acetabulum. Computer tomography readily confirms and accurately localises intra-articular osseous fragments not clinically suspected and not shown on radiographs. Furthermore, CT following a reduction in posterior hip dislocation should be used to investigate the relationship of fracture fragments and help estimate their stability and congruity.

Computed tomography can show the anatomic orientation of post-traumatic hips prior to total hip replacement. Such information helps surgeons plan hip replacement procedures by showing the amount of bone stock present in order to seat the acetabular component. Following gunshot wounds, CT may show the radial spread of bullet fragments better than radiographs. The information derived from CT may help the surgeon decide whether or not to examine the hip.

Fractured neck of femur is a serious consequence of falls in the elderly, and is associated with high morbidity and mortality [16].

Delay in surgical treatment has been shown to significantly increase mortality [17], whilst undisplaced fractures may become displaced if unrecognised and untreated, requiring surgery associated with much higher risk [18].

The sensitivity of plain X-rays in detecting hip fracture is believed to be 90-98%, based on multiple studies [19][20]. More recent studies suggest that approximately 4% of patients with symptoms suggesting of a hip fracture but with a normal initial hip X-ray in the Emergency Department, in fact have an occult hip fracture [21][22]. As a result, where there is high clinical suspicion of hip fracture despite a negative X-ray (patients with significant pain or non-weight bearing after effective analgesia), alternative forms of imaging must be considered and a CT scan must be performed. Nevertheless, there are theoretical limitations (i.e., the potential to miss some fractures in patients with severely osteoporotic bone, owing to the resolution of the trabecular structure and where the cuts are taken in a coincident plane).

5. CT IN AVASCULAR NECROSIS OF THE FEMORAL HEAD

In the assessment of avascular necrosis, therapeutic decisions are based on staging and subsequent surgical decision is based on anatomy. Early diagnosis is based on MRI and eventually nuclear medicine. In stage II, avascular necrosis may become radiologically detectable thanks to bone sclerosis and cystic changes, with preservation of the articular surface of the femoral head. Stage III disease indicates loss of structural integrity of the articular surface and requires aggressive surgery such as a varus osteotomy. In stage IV, there is a loss of the structural integrity of the femoral head, requiring total hip replacement.

The contribution of CT with multiplanar projection in pre-surgical planning are the definition of the arc and area of the sclerotic bone in the femoral head with the extent of the remaining intact femoral head, the detailed assessment of the weight-bearing acetabular dome and, especially, along the posterior acetabular rim, frequently defining radiographically unsuspected involvement. This may help in defining repositioning osteotomies in a more precise pre-operative planning.

6. CT IN OSTEOARTHRITIS

A progressive deterioration and loss of articular cartilage characterise osteoarthritis at the beginning. Afterward, the spherical femoral head starts flattening in the anteroposterior and lateral zones. This migration can increase, even over a long time. Subsequently, the spherical head becomes more ellipsoid, biomechanical forces are impaired and the rate of joint destruction accelerates. Clinically, this phase is characterised by pain, increasing in duration and intensity, and by decreasing range of motion. Osteotomy can be considered the best procedure to treat moderate disease, until total hip replacement in the case of severe pathology. Computed tomography with sagittal and coronal MPR helps to evaluate the major weight bearing surfaces with higher resolution detail than radiographs and freely from superimposed anatomical structures, allowing the detection of subtle narrowing of the rim. Furthermore, CT defines the entire surface of the femoral head better than axial radiographs, helping in the choice of total hip replacement over osteotomy and allowing more precise preoperative planning (femoral neck angulation, portion of head best suited to become a new weight-bearing surface).

7. CT IN HIP INSTABILITY AND FEMOROACETABULAR IMPINGEMENT

On the basis of radiographic assessment of femoral-acetabular joint, various surgical options can be taken, as not all parameters may change to a clinically relevant degree, with differences in pelvic orientation (Tannast parameters) [23]. Nevertheless, many pelvic radiographic measurements such as anterior and posterior acetabular coverage, the crossover sign, retroversion index and posterior wall sign can vary depending on pelvic orientation due to orthostatic/clinostatic acquisition of radiographs and due to X-rays tube inclination. This is why radiographic limits in evaluating pelvic abnormalities are mandatory, to avoid mistakes in decision-making and in the execution of joint-preserving surgery of the acetabulum. On the contrary, CT allows for the evaluation of these parameters independently from the position of the patient and the pelvic tilt and, for this reason CT, should be used in pelvic pre-operative evaluation.

Similarly, focal anterior over-coverage, or “cephalad retroversion,” can be difficult to distinguish from true acetabular retroversion on radiographs. CT also allows for defining the location of focal pincer along all the acetabulum. Distinguishing these lesions is critical, since the treatment plans and approaches for these two conditions are different.

In CT images, the alpha-angle and beta-angle measurements are more accurate than in the axial-view radiographs, as you can correctly choose the plane on which the cam lesion is more prominent. Mostly, the alpha-angle can be measured in radial reconstruction. The beta-angle is formed by the line connecting the centre of the head to the point at which sphericity is lost (same line as that used for the alpha-angle) and the line connecting the centre of the head to the edge of the acetabulum. It provides a rough assessment of the interaction between the cam lesion and acetabular over-coverage on a single plane.

Cam deformity is an osseous prominence that lacks epiphyseal sphericity and a decreased head-neck offset, sometimes also with epiphyseal retroversion (pistol grip deformity). Cam deformity may be depicted on the Dunn lateral radiograph, but the true topography and, above

all, the extension of cam along the head–neck junction may be only fully appreciated and measured with CT imaging. Furthermore, CT scanning helps to identify cam’s variants (accessory face, reactive plate) that represent entities with clinical relevance even if not fully understood. This information of the size, site and extent of the cam morphology is critical, as an osteoplasty must restore sphericity and offset in all planes and may affect the selection of an open versus arthroscopic approach. Milone et al. [24] demonstrated that an automated 3D CT-based imaging software was even more accurate than conventional CT, in identifying the location and magnitude of cam lesions in order to plan the surgical approach. Bedi et al. [25] applied similar 3D CT-based imaging software technology to quantify the location and topography of the cam lesion and demonstrate predictable improvements in range of motion with surgical treatment of the deformity.

An area of increasing interest has been the application of novel 3D CT-based imaging software, not only to quantify femoral and acetabular deformity, but also to perform a dynamic analysis to determine the location of mechanical conflict that reproduce symptoms. The beta-angle was an attempt to investigate the additive relationship of cam deformities and acetabular over-coverage on a single spatial plane. Hips with impingement should tend toward negative beta-angles, where the edge of the acetabulum overlies the cam deformity, while hips without impingement lesions should have values ranging between 20° and 40°. The 3D evaluation of the impingement surface, corresponding to the beta-angle in the space, has led to design the omega-e and omega-surface. Patients with high alpha proximal femur angle may not have symptoms when coupled with an acetabulum with low central-edge angles or viceversa. Nevertheless, the true clinical reliability of these spatial evaluations should be still assessed.

For all these reasons, CT is very precise for defining the dynamic and static abnormalities in a young patient with hip pain and should be used in joint-preserving surgery of the acetabulum.

8. CT IN HIP ARTHROPLASTY AND METAL ARTEFACTS

Following total hip replacements, patients may develop painful prosthetic joints. CT is important in evaluating hip replacements despite the presence of metal artefacts. Since the inception of CT, numerous methods have been proposed to suppress metal artefacts with varying degrees of success.

The presence of high atomic number materials (e.g., prosthetics, dental fillings) in CT images may cause severe artefacts. These artefacts present as streaks and dark areas in the image and are due to beam hardening and scatter. As the X-ray passes through the body, low energy X-ray photons are attenuated more easily and the remaining high energy photons are not attenuated as easily. Compared with low atomic number materials such as water, metals have a dramatically increased attenuation at lower energies. For low energy X-rays, attenuation is primarily due to the photoelectric effect. At high energies, attenuation is primarily due to Compton scatter and is inversionally proportional to the beam energy. Compton scatter causes X-ray photons to change direction (and energy) and thus end up in a different detector. This creates the greatest error when the scattered photons end up in a detector that otherwise would have very few photons. In particular, if a metal implant blocks all photons, the corresponding detector element will only detect scattered photons. Scatter

also becomes more significant with an increased number of detector rows, as a larger volume of tissue is irradiated. Now, there are many kinds of algorithms of reconstruction to reduce these metal artefacts. The crucial point of these algorithms is an iterative loop where the output correction image is subtracted from the original input image. The resulting image can then become the new input image and the process can be repeated. The first step is to threshold the input image to create a metal-only image. The metal-only image consists of all pixels set to zero, except for those pixels categorised as metal. This image is used to identify the projections within the sinogram data that have contributions from metal. If no large clusters of metal pixels are present in the image, no further processing is performed. Recently, novel imaging techniques have been introduced that are capable of reducing the effects of artefacts on scans and improving image quality. In addition, several companies have developed dedicated software packages for 3D image analysis (e. g. Mimics Innovation Suite, Materialise N.V., Leuven, Belgium or AQ implants, Ahrensburg, Germany) making it possible to further enhance the quality of the images and to incorporate novel analytic tools for characterising the defect and the remaining bone stock. These companies provide a specified scanning protocol that can be used by radiologists for data acquisition using metal artefact reduction modes. Consequently, the data are sent to the company for virtual reconstruction of the diseased pelvis by means of segmentation. Once the initial segmentation is performed, various algorithms help the user make adjustments, including edge detection, smart separation of bones from other structures and closing gaps. Despite this advanced technology, the process of segmentation still requires stringent quality control and manual corrections by an experienced user. This can be done through projecting the segmented bone contours onto the original images and editing them where required. Eventually, a detailed protocol is sent to the surgeon, including a proposal for an endoprosthetic reconstruction where required.

CT is superior to radiography in detecting, localising, and quantifying osteolysis around the acetabulum, which is especially helpful in patients who are being considered for revision arthroplasty.

Its particular importance to orthopaedic surgeons includes:

- whether there are cavitary or segmental defects (i.e., holes surrounded by bone or extending through the bone), especially posteriorly and superiorly;
- whether there is pelvic discontinuity (i.e., the superior and inferior portions of the socket are discontinuous).

On the femoral side, fractures, bone loss at the proximal femur (i.e., the calcar) and loss of the normal diaphyseal tapering are important for surgical planning.

CT can depict peri-implant fluid and soft-tissue masses that may be completely hidden on radiography. Ossified masses are usually well visualised on radiographs, but multidetector CT allows more precise localisation of these masses, definition of their extent and determination of whether they bridge the joint.

Surgeons preparing for acetabular component revision should be aware of the limitations associated with plain radiographic acetabular defect analysis. Nevertheless, currently-used acetabular bone defect classifications are mainly based on the interpretation of antero-posterior radiographs of the pelvis. However, multiple studies have demonstrated that a simplified analysis based on a single radiograph is not suitable to reliably detect

periprosthetic osteolysis and measure its dimensions, even with the additional use of iliac and obturator oblique views to better visualise bone defects. In particular, small periprosthetic defects located in the ischium or the acetabular rim were hard to detect on a single radiograph with a sensitivity of approximately 15% only [26]. Inter-observer reliability in the radiographic assessment of periacetabular bone defects has been demonstrated to be low with different surgeons not agreeing on what constitutes an osteolysis and what does not [27]. This is why surgeons preparing for acetabular component revision should be aware of the limitations associated with plain radiographic acetabular defect analysis.

Therefore, computed tomography has been advocated as an appropriate tool for acetabular defect analysis. Several research groups were able to demonstrate that CT analyses are capable of adequately detecting osteolysis and reliably measuring the dimensions of periprosthetic defects. Depending on the analysis technique and the artefact reduction mode used, a sensitivity of 74–98% has been described for both the detection of large and small defects [28][29]. Using CT as the gold standard, several authors were able to show that, in many cases, plain radiographic analysis was not sufficient in detecting periprosthetic acetabular osteolysis with an overall sensitivity of just 58–78% [30][31].

In literature, the Paprosky classification is the most widely used system for reporting outcomes after acetabular component revision and osteolysis [32][33]. It distinguishes six different defect types depending on the defect size and location and the capability of the acetabular walls and anterior and posterior columns to support a cementless hemispherical press-fit cup. Three-dimensional CT or MRI based image analysis might potentially be able to deliver the desired information, but their use in patients with metallic implants has so far been limited due to the presence of artefacts. The volume of the acetabular defect can be measured in cm³ (ml) allowing the surgeon to determine the size of acetabular augments or amount of bone graft needed for reconstruction. Furthermore, radial acetabular bone loss (in mm or %) can be estimated, helping the surgeon to determine if the remaining bone stock of the acetabulum is supportive of a pressfit implant and whether the anterior and posterior columns are intact. Finally, an analysis of overall bone thickness and cortical thickness can be provided, which makes it possible to anticipate what osseous structures are supportive of implants or screws. Novel software tools not only provide the possibility of anticipating the intraoperative reality in more detail, but may also make the development of defect-specific monoblock acetabular implants possible in case the remaining bone stock does not support a standard implant. However, even these novel software tools do not provide the possibility of an automated defect analysis. The process of segmentation has to be manually controlled and adjusted, if necessary. Consequently, the quality of the final 3D reconstruction and the deduced defect analysis are highly dependent on user experience. Therefore, the final steps in evaluating the quality of the provided analysis and integrating it into a medical treatment plan have to be carried out by the surgeon himself. Despite all these advantages, routine CT-based defect analysis has still not gained wide popularity, mainly due to higher costs and higher radiation doses compared with conventional radiographic examination. In addition, further studies have to confirm whether these novel analytical tools are capable of improving the reliability and validity of currently used defect classification schemes.

ABSTRACT

The introduction of the three-dimensional (3D) fluoroscopy brought new intra-operative imaging possibilities for the orthopedic surgeons, aiming at the improvement of the conventional fluoroscopy. Different authors demonstrated a high reliability of this technique for the evaluation of articular fracture reduction, for the presence of articular gaps and for implant positioning. The performances of 3D-fluoroscopy were estimated to be comparable to CT-scan and significantly superior to 2D fluoroscopy. The most favorable indications in pelvic and hip surgery comprehend both traumatic and elective surgery. Pelvic ring and acetabular fractures along with femoro-acetabular impingement are the fields where 3D-fluoroscopy more satisfactorily operates at the moment. For best performing this procedure it's essential a special care for patient's positioning, as any radio-opaque disturbance unfavorably influences the result. Moreover, further developments of 3D fluoroscopy with the support of secondary modeling softwares will be introduced in the next years, expanding its utilization.

Keywords: 3d fluoroscopy, intraoperative imaging, hip surgery

INTRODUCTION

Three-dimensional (3D) fluoroscopy has been developed in the last two decades to improve surgeons' intraoperative capability of understanding complex anatomy [1, 2]. The aim of this technology is to fill the gap between the highly accurate pre-operative imaging

regularly available with a CT scan, and the intra-operative low quality images of conventional fluoroscopy. Main concerns of 2D-fluoroscopy are well perceived by clinicians and mainly consist in the difficult assessment of articular fractures displacement and implants positioning [3]. Irregular anatomy, bone overlapping and soft tissues interposition are the principal bewildering factors for the conventional fluoroscopy. For those reasons and for their scarce maneuverability, pelvis and spine are considered the most problematic areas to examine. However, it's supposed that conventional devices can properly afford most of the cases.

Before the introduction of 3D-fluoroscopy the only way to detect sub-optimal reductions or minimally protruding intra-articular implants was the post-operative radiographic or CT control, leading to complications or an even more undesirably secondary surgery [4]. Thus, intra-operative diagnostic accuracy has gained more attentions among the development of new technologies. The best possible approach would be the setting of intra-operative CT scan as it happens in some very advanced trauma centers, though this solution still remains hypothetical for the greatest majority of hospitals. Moreover the radiation exposure for a CT scan is considerably higher compared to fluoroscopy. Navigation systems also provide surgeons further assistance for orientation in complex anatomy, but generally they consist in sophisticated devices, needing accurate pre-operative settings, eventually resulting less functional for daily practice.

3D-FLUOROSCOPY TECHNICAL ASPECTS

Conventional radiography produces a single-plane image of the anatomic segment positioned through the electron beam. To obtain different projections the operator can either rotate the patient or the instrument; following this concept the worldwide standard in intra-operative hip imaging has been represented by the C-arm, an efficient device that can easily rotate for 180° or more around the patient, maximizing the possibilities of radiographic projections. Along with that, the fluoroscopic intensifier efficiently limits the radiation exposure for the patient and the operators. Despite the optimal mechanism, it's a common feeling for the orthopedic surgeons that conventional fluoroscopy still have relevant limitations in clearly depicting structures in complex situations. The limits for the diagnostic accuracy are unfortunately intrinsic of the technique.

The first issue is dealing with the artifacts that often emerge from conventional scans, when the combination of soft tissues and air tend confuse the field. For this reason, pelvic or spinal surgery are chronically affected by the phenomenon and very little can be done for dealing with it. Furthermore, another limit is the bi-dimensional representations that cannot accurately reproduce articular surfaces. Since this problem becomes more significant as the joint space gets hollow and irregular, it's clear that for segments like talus, hip and spine is frequently achieved a sub-optimal intra-operative imaging.

The development of the 3D C-arm aimed at the resolution of these limitations, while maintaining an acceptable radiation dose for the patient. The principle on which the 3D-fluoroscopy lays is a software-based multiplanar reconstruction obtained by rotation of the arm. During the rotation an established number of images are acquired, each one at a slightly different orientation.

Figure 1. A modern 3D C-arm.

Then, an on-board software combines the data and provides a three planar scan of the analyzed volume, mocking a CT scan. Moreover, the devices usually show an animated clip of the rotating analyzed volume (Figure 1). Manufacturers follow two principal construction philosophies, so that 3D C-arms are classified into isocentric and non-isocentric devices. Simplifying, an isocentric device rotates around the subject in a perfectly circular movement, while the non-isocentric follows an elliptical path. For a C-arm to be classified as isocentric all the x-ray beams collimate through the same center all along the rotation, so the distance between the source and the intensifier is maintained constant. The minimization of distortions and a constant image size are the main goal of this solution. For non-isocentric C-arms the combination of rotation and elliptical orbit requires more elaborated software calculations, whereas the main advantage is the reduction in the amount of rotation needed. Up to date, there isn't any absolute supremacy among the available devices on the market, as each one offers the highest standards. The present excellences generally provide fully digital 1024x1024 resolution, time of scan less than 60s, variable 3D reconstruction modes on screen, full data export and many others [2, 5].

LITERATURE

Since the introduction of 3D-fluoroscopy, several efforts have been made to prove its advantages in surgical theatre; yet, it's still challenging to demonstrate the subjective additional diagnostic value commonly perceived. Outcomes heterogeneity, different scoring protocols and different examined variables are the main limits for a bright scientific support from the review of the existing literature.

In order to assess the level of 3D-fluoroscopy accuracy, most of the authors compared its preciseness to conventional techniques as 2D-fluoroscopy, X-ray and CT-scan. Analyses were made both on cadaver and in clinical studies. Condensing the available cadaver studies, it emerges that usually authors produced various articular fractures artificially or by applying forces resembling major traumas. Fractures reductions were performed under conventional 2D-fluoroscopy, then the achieved results evaluated with 3D-fluoroscopy. At the end of the

process the specimens were dissected and the discrepancies between the two imaging methods were observed. Moreover, a CT-scan was frequently performed prior to dissection and added for comparison. Modifications from this ideal scheme can be found in literature. When in-vivo studies were conducted, a combination of 2D and 3D-fluoroscopy was employed during the operations. Some authors performed 3D-fluoroscopy as final control for detecting any defect in reduction or fixation, some other ones during the procedure. One of the most interesting information obtained by these last studies is the rate of corrections needed after the 3D-fluoroscopy check, once that controls with conventional fluoroscopy were considered acceptable. Therefore, these corrections were performed after inaccuracies detected only by 3D-fluoroscopy and not perceivable on 2D-fluoroscopy, which is indeed the real worth of this technology. The main causes for resetting a finished fixation were implants suboptimal position and excessive step-offs or gaps in articular surface. In several studies, 3D-fluoroscopy showed to provide a clearer visualization of those defects when compared to 2D fluoroscopy and to X-ray, producing a higher rate of intra-operative corrections [1, 5-7].

Some authors also tested the diagnostic accuracy of 3D-fluoroscopy compared to conventional fluoroscopy, X-ray and CT scan. Summarizing the protocols adopted, 3D-fluoroscopy seems to have better, or at least equal, performances relatively to the first two techniques. Furthermore, diagnostic accuracy was found similar to CT-scan in most of the cases, which attests a considerable level of performance. Direct consequence of this reliability is the chance of sparing post-operative CT controls when doubts about reduction or implants positioning still exist after surgery. Advantages in diagnostic accuracy seems greater in bigger and more complex joints, when anatomy gets more irregular and articular surfaces intersect on plain radiographs [5, 8, 9]. As previously stated, existing studies comparing efficacy of conventional X-rays against 3D-fluoroscopy give to the latter a slight advantage, although scoring systems and adopted protocols were not homogeneous [5]. As supported by statistics, opinion leaders concluded that the most valuable field of 3-D fluoroscopy versus X-ray was in detecting articular gaps [10].

A significant contributing factor for choosing 3D-fluoroscopy for complex surgeries consists in the “spatial awareness” that can be obtained from reconstructions, not only for the poli-axial views that mirror the CT, but also for the immediate virtual 3D view available. Every surgeon approaching this technology appraises this feeling, though it is simultaneously hard to communicate or estimate it.

APPLICATION FIELDS

3D fluoroscopy best performs where anatomy gets more complex. Typically the most demanding segments are irregular anatomical districts as spine or pelvis and highly displaced and comminuted fractures (Figure 2).

These two extremes represent the perfect examples for an ideal use of 3D-fluoroscopy, though there isn't any black or white situation for its employment.

Figure 2. Pedicle screws of a lumbar stabilization.

Focusing on hip and pelvis, an increased spatial awareness could be a valuable support both for traumatic and elective surgery. For instance, the pelvic ring is a common site of fracture in major traumas whereas surgical treatment still remains demanding. If anterior stabilization is generally achieved by external fixation or plating without any remarkable difficulties, posterior fixation could hide some delicacies due to the abundance of critical structures surrounding the bone. The main threats to avoid for posterior synthesis are the lumbosacral plexus, the major vessels of the iliac fossa, and the intra-peritoneal organs. A well-established method for posterior fixation consists in percutaneous placement of sacroiliac screws under fluoroscopic guidance, which allow for a rapid and effective stabilization without the invasiveness of open surgery. Some criticisms still exist about this technique, as for achieving a good result both optimal patient positioning and fluoroscopy maneuvering is mandatory. Moreover, fulfilling these conditions does not always guarantee a satisfying result in terms of imaging quality, due to soft tissues or internal air. For safe practicing sacral foramina have to be identified in outlet view, in order to avoid the plexus during screws placement; then, the antero-posterior positioning has to be repeatedly checked in inlet view during the procedure. Nevertheless, the view of sacral foramina is often confused, especially in displaced fractures and/or obese patients, increasing the risk of iatrogenic lesions, incorrect placement of hardware and sub-optimal fracture reduction. Considering this background, a significant support should come out from the employment of 3D-fluoroscopy (Figure 3, Figure 4).

Really, if there's the chance of performing a 3D scan in order to clear up any uncertainty in reduction or in implants position, it should be done, as it is demonstrated that the diagnostic power is similar to the one of the CT-scan [11-13].

Following the same principles of safety and accuracy, also acetabular fractures could considerably benefit from 3D-fluoroscopy, as this anatomical district meet all the characteristics for a difficult imaging.

Figure 3. Irregular sacral anatomy is difficult to depict on conventional 2D radiograms.

Figure 4. The 3D-fluoroscopic scan helps in detecting dangerous structures.

Since the reduction and fixation of every articular fracture has the goal of reducing the risk of post-traumatic osteoarthritis, achieving a perfect congruence of the articular surface is mandatory. When a direct visualization of the entire joint is not available as it frequently happens in acetabular fractures, the role of the imaging become primary. In such cases a big help can be obtained by the multiplanar reconstructions produced by the 3D fluoroscopy scan, for detecting step-offs, gaps and dangerous misplaced screws (Figure 5, Figure 6) [14, 15].

Figure 5. Checking of intra-pelvic screw protrusion in posterior acetabular wall plating.

On the other side, the applications in elective surgery of hip and pelvis are less common, since pre-operative imaging is often fulfilling and the techniques more standardized. However, some exceptions could be found in the developing field of mini-invasive surgery; it is easily understood that a big exposure should rarely profit from accurate intra-operative imaging, as the structures are generally under direct view. On the contrary, since tissue sparing techniques often produce hollow cavities where orientation becomes complicated, an additional aid is frequently requested. In prosthetic surgery this is variously achieved, having in navigation systems probably its most effective example. In this case 3D-fluoroscopy could hardly become competitive. Conversely, the other branch of interest where a 3D intra-operative imaging can produce tangible advantages is the treatment of femoro-acetabular impingement. We know that the clinical entity of hip impingement can be produced by multiple factors, although two main types are scholastically described: cam and pincer.

Figure 6. Acetabular fracture with an unexpected intra-articular fragment.

For both of them the pathophysiologic mechanism that produces pain, functional limitations and articular damages takes place in prolonged collisions between bony excesses from acetabular side (pincer), femoral side (cam) or a combination of the two. Surgical treatments have the aim of reducing the redundant bone from each side, while minimizing the procedure invasiveness. This strategy let the development of the two most diffused approaches, which are hip arthroscopy and “mini-open” technique. In both techniques, a common critical aspect is represented by the decision of the amount of bone tissue to be removed, because no direct control of impingement can be accurately made, even under conventional fluoroscopy. An insufficient correction won’t resolve the symptoms, while in the worst of the cases an excessive bone removal could produce a serious hip instability [16-18]. With this background, the application of intra-operative 3D-fluoroscopy may help the surgeon to detect more precisely the areas of impingement and to better evaluate the amount of correction performed. Moreover, in a hypothetical protocol a pre-operative scan could be made for planning the resection, while at the end of the procedure a new 3D-scan could verify if an adequate result has been achieved.

As mentioned, there are no actual limitations for 3d-fluoroscopy employment and this statement is valid for hip and pelvis as well; other possible applications could comprehend bone deformities, other conservative surgeries, complications of routine operations and so on.

PATIENT'S POSITIONING

For best performing a 3D-fluoroscopy, great importance is given to the patient's optimal position and even more to the surrounding hardware. Commonly surgeons pay lot of attentions for the appropriate setting of the operative room, in order to reduce the risks of fluoroscopy dysfunctions due to interposed radio-opaque objects.

There's a strong association between the amount of tissues or dense material that the electron beam has to cross and the quality of the final image. If this statement regards traditional 2D fluoroscopy, it becomes even firmer for 3D fluoroscopy. The principal reason is the necessity of a rotation around the target between 120° and 180°, which unfortunately tends to include undesired objects in the field. In extremities' surgery the problem is easily overcome by radio-transparent supports and isolation of the limb, while the scarcity of soft tissues contributes to perform good quality imaging (Figure 7).

The issue is actually to deal with central segments, as it happens in spine or hip and pelvis surgery. In these areas the problems occurring for a complete and clear scansion frequently cohabit, as soft tissues among with abdominal gases use to create artifacts, while surgical table is not often entirely radiolucent.

Figure 7. Scarcity of soft tissues provides high-quality imaging.

Even minor metal parts like sustaining lateral bars, gelatins or cables have the power to alter the quality of the 3D-fluoroscopy scan (Figure 8, Figure 9).

In hip and pelvic surgery an excellent solution is the employment of a carbon fiber table, completely radiolucent and without metal sidebars (Figure 10). Moreover, the table should be offset as much as possible from the central sustaining column, in order to create an empty space right below the pelvis, permitting the C-arm to freely rotate around the patient. Although this setting provides the best results in reducing external disturbs, it's hard to employ it for all the cases, as it works for supine or prone positions only. For lateral approaches the ideal use of radiolucent sustains should be pursued, even if rarely available at present time.

Figure 8. Other metallic objects can affect image quality.

Figure 9. Severe disturb from several surrounding metal parts, causing a useless scansion.

Figure 10. An example of completely radiolucent carbon-fiber surgical table.

An interesting field of application for 3D-fluoroscopy is hip arthroscopy, which is gaining popularity; beside the potential advantages in detecting bone corrections, there's a troublesome difficulty in avoiding external disturbs.

The obstacle comes from patient's position and the necessity of traction of the lower limbs, as traction table frequently includes metal braces and joints that lay into the C-arm scan. The ideal solution would be a completely radiolucent traction table or, at least, a big reduction of disturbing dense parts around the pelvis.

Once more, the two main aspects to be pursued for optimal patient's positioning before performing a 3D-scan are the reduction of interposed material and the chance for the C-arm to rotate around the subject without collisions.

The accurate setting of the surgical theatre is then of utter importance, as it is demonstrated that the presence of artifacts lowers both specificity and sensibility of 3D-fluoroscopy, until causing it to be useless [5].

CRITICAL ISSUES

The technology for intra-operative 3D-fluoroscopic scans has significantly advanced in the last twenty years, up to the last released systems that are highly optimized in terms of efficacy and versatility. Although good performances are relatively easy to obtain and advantages are clear, there are still some issues that limit the widespread diffusion of the technique.

For instance, the acquirement of high quality images is a proper example of tricky practice, as it appears reasonably simple for everyone in most of the cases.

However, even if the C-arm works automatically once started, the role of the radiologic technologist is still central for the success of obtaining a true diagnostic scan without

confounding factors. Optimized machinery settings along with accurate patient's positioning produce substantial modifications in imaging quality, often making the difference over the millimeter involved in crucial clinical decisions. Therefore, for a convincing experience with 3D-fluoroscopy it is recommended to enroll trained personnel with adequate experience (Figure 11).

Figure 11. Confounding factors can be many in an ordinary operating room.

Some concerns exist about the amount of time employed to perform the entire scan process in the utilization of the 3D-fluoroscopy. Even if the true operative time of the machineries is less than a couple of minutes, the whole positioning of the C-arm and its semi-automatic verification motions it's somewhat time-consuming.

Actually, most of the time spent for obtaining a scansion is wasted for the correct setting of the environment. Again, for the optimization of the process and to limit this dissipation is recommended to engage properly trained staff, used to regularly practice.

At the moment, the main practical difficulties in the utilization of the 3D fluoroscopy are related to the equipment encumbrance, along with the necessity of circling the involved anatomical region, and to the requisite of radiolucent hardware.

FUTURE IMPROVEMENTS

Since the introduction of the 3D-fluoroscopy it has been immediately clear the additional support given to the surgeon for better comprehend complex intra-operative imaging. This was surely the initial aim successfully achieved by the creators, and the following improvements brought this technology to the standards we currently know. However, the massive digital evolution we are experiencing could really expand its limits of application, opening for new and fascinating possibilities in the immediate future.

For example, the output files generated by the device could be collected and manipulated for obtaining additional information more than simple observation.

The potentiality of modern softwares allows in fact a quick secondary processing of the raw data, in order to generate virtual models to work on (Figure 12).

Applications of this process are sensibly growing because of the increasing awareness of the digital world by the orthopedic community, and because researchers are getting more confident with informatics.

Figure 12. Example of a virtual model of the hip.

When a virtual model is imported into a CAD (computer assisted design) software, a great amount of operations could be run on it to produce animations, cuts, sections, virtual explorations and so on. Moreover, a recent idea of creating collision models for the intra-operative control during hip impingement treatment is now on course of development. However, it is of utmost importance that all the secondarily revised data can be live-processed in order to guarantee the chance of adjustments during operations. The live action is indeed the real added value that makes the difference between 3D-fluoroscopy and the other diagnostic procedures now available. Thinking about the future, it cannot be excluded the opportunity to apply the concepts of virtual rendering also in the pre-operative phase, in order to increase diagnostic capability with tolerable radiation exposure. These hypotheses could bring the 3D-fluoroscopy to new experimental employments, until leading to possible overlapping with CT-scan. A further attractive topic in orthopedic surgery regards 3D printing, a branch in remarkable expansion with great potentiality. Until now, the creation of printed models has passed through the segmentation of a CT-scan, frequently bringing out the question of risk-benefit assessment when not strictly necessary for diagnostic purpose. If sufficiently implemented and optimized, there would be the concrete possibility for 3D-fluoroscopy to supply adequate imaging destined to 3D printing; along with that, even the indications of printing could be extended to the cases that wouldn't have benefited of CT scan.

CONCLUSION

The last couple of decades has seen the introduction of 3D-fluoroscopy and its following evolutions to nowadays' standards. Even if several authors proved the effectiveness of this technology along with the consequent advantages, there is not yet the broad diffusion that can be reasonably expected. A first explanation could be found in the additional costs related to the machinery acquisition, which are considerably higher than conventional fluoroscopy. However, if put aside the investment issue, it could be supposed that 3D-fluoroscopy hasn't spread so far into the surgeons practice for a lack of familiarity and insufficient awareness of its potential. Definitely the wish is to encourage the production of lot more studies on the topic, both for strengthen the scientific validation of known benefits, and for investigate new applications in the computer era.

ABSTRACT

Hip pain has different etiologies in adults and children. In adults hip pain may be caused by intra-articular disorders (such as avascular necrosis, arthritis, loose bodies, labral tears), periarticular disorders (such as tendonitis and bursitis) or extrarticular pathology (such as referred pain from lumbar spine, sacroiliac joints and nerve entrapment syndromes). Imaging of the hip needs to be complementary to the clinical history and physical examination because it is well known that imaging findings do not always correlate with the presence of pain and vice versa.

MRI is the imaging modality of choice for evaluation of hip joint pain, due to its contrast and resolution for soft tissues, for the absence of operator dependence and for not needing ionizing radiation. It offers information regarding occult bony and cartilage injury such as stress fracture, avascular necrosis and osteoarthritis, as well as soft tissue abnormalities such as muscle tear and bursitis.

MRI provide a useful assessment of patients in whom a femoro-acetabular impingement (FAI, Cam and Pincer types) is clinically suspected. A high resolution, non arthrographic technique can provide preoperative information regarding the presence and anatomic site of labral and cartilage abnormalities.

The MRI arthrography is superior to conventional MRI for detecting labral tears and acetabular cartilage defects; it also shows higher interobserver agreement. Both modalities (with and without arthrography) have comparable results for femoral cartilage lesions.

MRI helps also surgeon to decide which patients may require an arthroscopic versus an open surgical technique.

INTRODUCTION

The hip is a stable, major weight-bearing joint with significant mobility.

Hip pain has different etiologies in adults and children. In adults hip pain may be caused by intra-articular disorders (such as avascular necrosis, arthritis, loose bodies, labral tears), periarticular disorders (such as tendonitis and bursitis) or extrarticular pathology (such as referred pain from lumbar spine, sacroiliac joints and nerve entrapment syndromes). Imaging of the hip needs to be complementary to the clinical history and physical examination because it is well known that imaging findings do not always correlate with the presence of pain and vice versa.

MRI is the imaging modality of choice for evaluation of hip joint pain, due to its contrast and resolution for soft tissues, for the absence of operator dependence and for not needing ionizing radiation [1]. It offers information regarding occult bony and cartilage injury such as stress fracture, avascular necrosis and osteoarthritis, as well as soft tissue abnormalities such as muscle tear and bursitis.

MRI provide a useful assessment of patients in whom a femoro-acetabular impingement is clinically suspected. A high resolution, non arthrographic technique can provide preoperative information regarding the presence and anatomic site of labral and cartilage abnormalities. MRI helps surgeon to decide which patients may require an arthroscopic versus an open surgical technique.

HIP ANATOMY

The hip joint is a ball-and-socket type joint and is formed where the femur meets the three bones that make up the pelvis: the ilium at the rear, the ischium at the lower front and the pubis above it. At the age of 15-17, the three parts begin to fuse. Their fusion forms a cup-shaped socket known as the acetabulum, which becomes complete at 20-25 years of age. This involves the stability of the hip. The depth of the acetabulum is further increased by a fibrocartilaginous labrum attached to the acetabulum. Additional stability is provided by the strong joint capsule and its surrounding muscles and ligaments. The hip joint capsule is a dense, fibrous structure which includes the iliofemoral, pubofemoral, and ischiofemoral ligaments. These ligaments along with the ligamentum teres and the labrum help give stability of the hip. The fibrous capsule of the hip joint is covered internally by the synovial membrane, while the hyaline cartilage covering the articular surface of the femoral head acetabulum several important intra-articular structures can be identified by MRI. The acetabular margin is surrounded by a fibrocartilaginous labrum which is identified through better arthro-MRI [2].

1. Femur

The femur is the longest and most robust skeletal segment of the body. It consists of a head, a neck and a diaphysis, almost cylindrical for almost its entire length, whose lower distal end, the most massive, presents two condyles and articulates with the tibia.

2. Fibrous Capsule

The fibrous capsule is robust and thick put on top of the contour of the acetabulum, to 5-6 mm of the base of the lip, creating in this way the perilabial withdrawal, forward on the outer edge of the lip and, in correspondence of the notch of acetabulum, on the transverse ligament of the acetabulum and on the margin of the obturator foramen. It is inserted distally along the anterior margin of the femoral neck at the level of the intertrochanteric line.

It is very vascularized and for this reason it appears pinkish arthroscopically, while it appears hypointense after being administered through intra-articular contrast. The fibrous capsule has a greater thickness at the level of the upper part and the anterior, while it appears thinner in the back inferior. The outer surface of the fibrous capsule is irregular and is covered by various muscles, connected to the passage of large psoas and iliac muscles.

3. Acetabular Labrum

The acetabular labrum functions as a shock absorber, joint lubricator, and pressure distributor. By increasing the surface area of the acetabulum of 28%, the acetabular labrum helps to distribute load. Furthermore, it works as a seal to keep the synovial fluid within the articular cartilage and maintain fluid pressure.

Numerous studies have been conducted to investigate MRI of the asymptomatic hip, the acetabular labrum in particular. Investigators have identified many anatomic variants, including labral variants, several sublabral sulci, perilabral sulcus, transverse ligament labral junction sulcus, and anterosuperior cleft. These variants can be confused with labral abnormalities.

The labrum varies 2–3 mm in thickness. It is thickest in the superior and posterior aspects and widest in the anterior and superior aspects of the hip.

Labral shape becomes more variable with advancing age. MRI of the hip may show normal anatomic variants of the labrum. The variants can be of the labrum itself or associated with the labrum. Anatomic variants can easily be mistaken for pathologic findings on MR images [3]. These types of labrum are:

- triangular, in most cases with sharp edge;
- roundish, with more or less sharp edge;
- irregular;
- in rare cases, it may be completely absent.

4. Ligaments

Ligaments that contribute to the joint stability are:

- the ligament of the femoral head (round ligament): is a flattened triangular formation which secures with its apex in the front and top of the dimple of the femoral head, and with its base on the notch of acetabulum through two beams, one for each side of

the notch; in the range between these two bony insertions it merges with the transverse ligament;

- iliofemoral ligament: triangular, rugged, begins at the front of the joint and is closely fused with the capsule. It sticks with the apex at the bottom surface the anterior inferior iliac spine and the base line to the intertrochanteric femoral line.
- ischiofemoral ligament: placed behind the articulation and arranged in a spiral, because from his ischium insertion is brought below and to the acetabulum, at the top and side of the rear face of the femoral neck;
- pubo-femoral ligament: is also triangular with the base of the hip bone at the level of eminence ileus-pectineal, upper branch of the pubic crest and obturator membrane; bottom merges with the capsule and the deep part of the medial ligament beam iliofemoral.

5. Synovial Membrane

The synovial membrane, very extensive, originates on the contour of the articular cartilage of the femoral head, by coating that part of the neck which looks inside the capsule; from the neck it is then reflected on the inner surface of the capsule, which covers both surfaces of the acetabular lip, sheathing the ligament of the femoral head and covering, at the end of the adipose tissue bearing content in acetabular pit.

6. Muscles That Act in Movements

Different movements are generated from different muscular groups. They are respectively:

- for flexion: psoas major and iliacus, helped by pectineus, rectus femoris and sartorius;
- for extension: great gluteus and extensor muscles of the thigh;
- for abduction: small and medius gluteus, helped by tensor fascia lata and by sartorius;
- for adduction: longus adductor, short and large, supported by frail and pectineus;
- for internal rotation: tensor fascia lata and front beam of the small and medium gluteus;
- for external rotation: shutter, twins and femur square, supported by piriformis, maximus gluteus and sartorius.

HIP MRI TECHNIQUE

The hip joint is difficult to image because it is not oriented in the standard planes of the body (axial, coronal, and sagittal), and there is significant variation in hip joint orientation from person to person too.

Patients are typically positioned supine on the examination table. Feet are internally rotated and gently immobilized with tape if necessary, with slight flexion at the knees.

Both hips are examined for suspected bilateral abnormalities, using the body coil with a large field of view to determine the extent of the lesions and to allow comparison between normal and abnormal side.

MR imaging is performed on 1.5 and 3 T scanners using a phased-array surface coil. Coronal T1 and STIR, axial T1 and fat-suppressed T2 sequences are obtained with a large field that includes the proximal femurs, the pelvis, and the sacrum. The remaining sequences use a small field of view and fat-suppression T2 sequences focused on the symptomatic hip [4].

The slice thickness is adjusted to be 4-5mm; thinner slices are used when more details are required.

Images are taken in the following sequences:

- scan views of the hip;
- coronal T1 WI and T2 WI images, performed in all case for localization of subsequent slices and planes, useful to delineate anatomy of the hip;
- axial T1 and T2 WI;
- coronal STIR WI;
- sagittal DP WI;
- if necessary T1 WI axial, coronal and sagittal sequences post intravenous bolus injection of Gadolinium DTPA (dose of 0,1 mmol/kg in neoplastic and inflammatory cases).

Recent studies have been focused on the role of diffusion weighted MRI because it does not need contrast medium administration.

HIP MRI ANATOMY

Coronal images provide optimal evaluation of the superior labrum, articular cartilage of suprafoveal femoral head and the cartilage over the lateral acetabulum. Hip abductors (and its origin), short external rotators, iliofemoral ligament and iliopsoas attachments are optimally evaluated in this plane too.

Sagittal images provide evaluation of the anterior labrum, articular cartilage of the femoral head and acetabular dome.

Axial images allow visualization of the anterior and posterior acetabular articular cartilage and of the labrum. Iliopsoas tendon (low-signal-intensity structure, anteromedial to the anterior labrum), bursa, sciatic, femoral and obturator nerves, continuity of ligament teres are also well visualized [5].

Some clinicians use a “sagittal oblique” imaging plane, oriented parallel to the long axis of the femoral neck, to evaluate for labral tears and femoroacetabular impingement [6].

The bone structures have homogeneous signal intensity: hypointense on T2-weighted images and hyperintense on T1-weighted sequences.

An intermediate-weighted non-fat-suppressed FSE sequence is favored for cartilages, providing accurate assessment of chondral defects, progressive degeneration and appearance of joint space before diagnostic radiographic imaging.

The intra-articular fat pad lies in the central portion of the acetabulum and has the highest T1 signal intensity of all the structures in the hip (rich of proteoglycans) [7].

The T2 map provides water content and collagen fiber orientation; in the deep zone of cartilage, near the subchondral plate, the relaxation times are shorter than closer to the articular face (higher order of collagen in the fibrous joint capsule).

MRI can correctly evaluate osteochondral lesions and subchondral bone (for potential stability of surgery), regularity of fibrocartilaginous labrum.

In 44–56% of asymptomatic hips, the labrum has low signal intensity in all MR sequences. Other MR signal variations include intermediate signal intensity on T1-weighted and proton density-weighted images (58%), intermediate signal intensity on T2-weighted images (37%), and high signal intensity on T2-weighted images (15%) The internal signal variation is more common in the superior and anterior aspects of the labrum [8]. The internal signal intensity may appear globular, linear, or curvilinear and may extend to the labral margins. The incidence of internal signal in general and of internal signal that extends to the labral margins increases with age. Therefore, the task of differentiating a normal labrum that contains internal signal that may extend to the labral margins from an abnormal labrum can be difficult and may require intraarticular administration of gadolinium contrast medium. In most cases (about 56% in asymptomatic patients) labrum presents homogeneous low intensity of the MR signal in its rear portion, while it becomes higher dense moving towards its most anterior portion [8, 9].

T1q or Gd-DTPA sequences discern mainly cartilage and its degeneration [10].

PATHOLOGIES EXPLORED BY HIP MRI

1. Transient and Migratory Osteoporosis

There is a group of conditions that have in common the development of self-limited, spontaneous and progressive pain accompanied by radiographic osteopaenia. This affects one or several joints, most commonly the hip, in different temporal succession.

MR imaging shows:

- bone marrow edema pattern involving femoral head, neck and sometimes the intertrochanteric region;
- inconsistent, mild involvement of the acetabulum;
- small joint effusion, invariably present;
- no focal changes typical of osteonecrosis are found.

Several authors consider transient osteoporosis as a mild variant of reflex sympathetic dystrophy or as a result of a transient ischemic insult to the bone [11].

2. Stress Fracture

The term refers to a failure of the skeleton to withstand submaximal force over time. Two forms of stress fracture have been defined:

- fatigue fracture is classically described in military recruits, athletes and runners in whom normal bone is exposed to repeated abnormal stresses;
- insufficiency fracture results when normal stress is applied to abnormal bone such as bone affected by osteoporosis or Paget disease.

MR imaging facilitates early diagnosis of stress fracture. It appears as:

- bone marrow edema, best depicted on STIR or T2 WI Fat SAT scans. The increased water content of associated medullary edema or hemorrhage results in high-signal intensity against the dark background of suppressed fat;
- fracture line: discrete low signal intensity line (when identifiable).

3. Loose Bodies

Free fragments or joint mice include free floating or adherent intrarticular fragments.

They are most frequently located in the acetabular fossa or in the anterior joint capsule recesses.

A cartilaginous loose body demonstrates low-to-intermediate signal intensity on T1 WI or PD WI images; the osteochondral ones presents a sclerotic rim.

Evaluation on donor site reveals a defect in the chondral surface of the femoral head or acetabulum.

4. Morel Lavallee Lesions

Post-traumatic fluid collections deep to subcutaneous tissue but superficial to fascia lata and iliotibial band, located proximally in the trochanteric region.

These lesions need a diagnosis on MR, in particular Type II and III (because on PD WI FSE images a non-acute hematoma can be disclosed) [12].

5. Hip Dysplasia

MRI is increasingly used for treatment planning and monitoring of more difficult cases of dysplasia. It is now used in the postoperative period after reduction and spica cast placement.

The following findings can be identified in MRI of DH [13]:

- shallow, dysmorphic, chondral, or subchondral acetabulum;
- retroversion and inadequate femoral head coverage (measurement of degree of covering);
- asymmetry of femoral heads;
- delayed ossification (discovered comparing femoral heads), unossified acetabular epiphysis [14];
- degree of femoral head position relative to acetabulum femoral head (and related subluxation or dislocation);
- labral hypertrophy (or mucoid degeneration or tear), morphology and position: its assessment is important for eversion or inversion after surgery [15];
- pulvinar, ligamentum teres or transverse ligament hypertrophy: fibrofatty proliferation prevents adequate femoral head reduction;
- remodeling of femoral head and development of a pseudocapsule when the femoral head is located upper and lateral to the shallow acetabulum;
- information about femoral head perfusion and probability of vascular necrosis after treatment.

Also bony and the cartilaginous acetabular index can be measured correctly by MRI, using an antero-posterior coronal view; these indexes are comparable to that measured in radiographs [16].

Additional findings on T1 and PD images includes hypointense joint effusion, hyperintense fat signal of the pulvinar and superolateral dislocation on coronal images [17].

6. Osteoarthritis (OA)

Hip osteoarthritis can be a difficult diagnosis because hip pain can radiate to back and leg, thus miming other conditions, such as sacroiliac joint dysfunction.

MR findings in this affection are:

- sclerosis: of femoral neck, acetabular rim or subtle periosteal bone;
- subcondral acetabular cysts (more in females than in males);
- sclerogeodes changes in femoral head and acetabular side (more in males than in females).

In females osteoarthritis is also reported with anatomic anomalies such as coxa valga or DDH [15].

MRI has been shown to be potentially useful to score progression of disease, using some semi-quantitative scoring systems that are nowadays available. Presence of collateral synovitis and inflammation can be performed with MRI. Quantitative evaluation of joint tissues, cartilage thickness or cartilage composition is possible too [18]. MRI detects early features of osteoarthritis when radiographs are still negative.

Four grades of OA have been described, based on the MR extent of disease:

GRADE 1: chondral inhomogeneity as attenuated chondral signal in T1 WI and PD WI FSE;

GRADE 2: inhomogeneity and discontinuity of the chondral surface, with hypointensity of the femoral head and neck on T1 WI images;

GRADE 3: grade 2 plus irregular morphology of femoral head and acetabulum, cystic changes and indistinct zone between femoral head and acetabulum;

GRADE 4: grade 3 plus femoral head deformity.

ADC ratio of the femoral metaphysis correlates with prognosis for the majority of inflammatory abnormalities.

7. Avascular Necrosis of the Hip (AVN)

AVN is a general term referring to the ischemic death of bone, not specific for a part of it. MRI is the most sensitive mean of diagnosing for AVN, representing the gold standard of non invasive diagnostic evaluation. It has several advantages and allows accurate staging by clearly depicting the size of lesions. It also detects asymptomatic lesions that are undetectable on plane radiographs, facilitating early treatment and better response, with 95% sensitivity [19].

Appearance of AVN with MR imaging is typically:

- reactive interface line: focal serpentine T1-hyper-intense line, which represents blood products, that surrounds edema. It is the most common and first sign of AVN on MRI;
- diffuse edema: low intensity in T1 occurs in advanced stages and is directly correlated with pain [20];
- double-line sign: a second serpiginous hyperintense inner line between normal and ischaemic marrow, which divides peripheral dark (sclerosis) and inner bright (granulation tissue) on T2 WI. This sign is also diagnostic [21];
- osteochondral fragmentation (rim sign);
- secondary degenerative changes.

The FICAT and ARLET classification of AVN uses a combination of plain RX, MRI and clinical features to stage vascular necrosis of the femoral head. Stages are:

- Stage 0: RX normal; MRI normal; no clinical symptoms.
- Stage I: RX normal or minor osteopaenia; MRI edema; pain typically in the groin region.
- Stage II: RX mixed osteopaenia and/or sclerosis with or without subcondral cysts, without any subcondral lucency (crescent sign); MRI characterized by geographic defect; pain and stiffness.
- Stage III: RX with crescent sign and eventual cortical collapse; MRI same findings of RX; pain and stiffness with radiation to knee and limb.
- Stage IV: RX final stage with evidence of secondary degenerative change; MRI same findings of RX; pain and limp [22].

8. Synovitis

Considered one of the most common causes of hip pain and limping in young children, synovitis is a self-limiting acute inflammatory condition affecting the synovial lining of the hip.

MRI features include:

- symptomatic hip joint effusion, synovial soft enhancement especially in T2 WI sequences;
- contralateral joint effusion (same signal, same features);
- synovial thickening, signal alterations and enhancement signal in T2 WI in soft tissue that surrounds synovitis.

There is usually no signal alteration in the adjacent marrow.

9. Synovial Chondromatosis

It is a monoarticular synovial-based cartilage metaplasia with development of intraarticular loose bodies, that may result in destruction of the hyaline cartilage and in progressive OA.

On MR images multiple ossified loose bodies are seen as foci of intermediate signal intensity. Nodules may demonstrate features of fatty marrow on T1 and T2 WI (and appear as parts of high signal intensity).

10. Muscle and Tendon Disorders

Muscle strain, muscle contusion, interstitial hemorrhage and hematoma (with related grade of evolution), but also sequelae of muscle injury are all well-defined features using MRI. Using this technique is possible to study grade and extension of intramuscular edema, assessing fibers' destruction or preservation. MR is useful for studying musculo-tendineous junction and fiber's retraction too [23].

11. Trochanteric Bursitis

The trochanteric (or subgluteal maxima) bursa becomes inflamed by repetitive irritation of the tensor fasciae latae, that slides over the greater trochanter. This a pathology is common in runners and athletes.

MRI shows a thickened, heterogeneous and/or capsulated fluid collection, which appears hyperintense on PD WI FSE images with regular isointense margin [24].

ARTRO-MRI

With the rise of hip-preserving surgery and hip arthroscopy over the past decade, MRI of the hip joint has been established as an important tool for making treatment decisions. MRI is performed in an increasing number of patients with suspected FAI to assess the morphology of femur and acetabulum and to detect lesions of labrum and articular cartilage. Many studies have shown that MRI arthrography is superior to conventional MRI for detecting labral tears and acetabular cartilage defects and demonstrates a higher interobserver agreement. For femoral cartilage lesions, both modalities show comparable results [25].

The MRI arthrography is superior to conventional MRI for detecting labral tears and acetabular cartilage defects; it also shows higher interobserver agreement. Both modalities (with and without arthrography) have comparable results for femoral cartilage lesions.

Surgeons are interested to know whether they will encounter extensive cartilage damage or non extensive cartilage at the acetabular rim during surgery, because, in the latter case, a complete removal of the acetabular cartilage lesions will be possible during surgery [25].

ULTRASOUND GUIDED AND THE APPROACH TO THE HIP JOINT

Interventional musculoskeletal ultrasound guided manoeuvres refer to a variety of invasive procedures performed percutaneously, covering diagnostic as well as therapeutic injection of joints, tendon sheaths or other peri-articular structures up to more complex manoeuvres like biopsies, removal of foreign bodies and intratumoral therapeutic injections. Ultrasonography has a very important advantage over other imaging methods because it allows the concomitant visualization of the target structure, the needle penetration and tip positioning as well as the contrast deposition [26].

To perform an ultrasound guided procedure, the patient should be supine. The examination is performed with a low frequency (3.5-7.5 MHz) linear array probe or using a convex one (2.5-5 MHz) for obese or muscular patients, in grey scale and Doppler mode (to better evaluate the relationship with the vessels and the nerve. The anterior (superior collicular recess) and the supero-anterior recesses are the most important in musculoskeletal ultrasound assessment because of the sensitivity in depicting synovitis [26].

Before starting the interventional procedure, an ultrasound evaluation of the hip joint must be repeated in order to reconfirm the diagnostic selection criteria for the invasive manoeuvre and to choose the most appropriate approach. The longitudinal antero-superior approach, having the femoral head as the target, is the better possible for drug deposition [26].

Under sterile conditions, a 20-22 G spinal needle is placed on the anterior-superior side of hip joint. After doctor wears sterile gloves, prepares patient's skin above the hip with antiseptic solution, and uses a sterile condom to isolate the transducer followed by application of sterile gel on the scanning area. The needle is introduced inside the anterior capsular recess at the level of femoral head and after femoral head contact, retraction of the needle tip of 1 mm is requested; then contrast is injected under direct visualisation with the ultrasound guide.

Once accurately identified the input point, is possible to administer paramagnetic contrast: it is gadoteric acid, used in doses between 10 and 20 ml, depending on the patient's

constitutional habitus. Immediately after the introduction of the contrast agent the patient is taken to the MRI room to perform MRI scans essential for a correct diagnosis.

MRI- arthrography is performed on a 1.5 T system, using a flexible four- channel body matrix phased-array surface coil and a six-channel spine matrix coil, generally integrated into the examination table [25].

The routine protocol for artro-MRI include the following sequences: a coronal T1-weighted spin-echo sequence (TR/TE); a coronal intermediate-weighted fast spin-echo sequence with fat saturation(T2-STIR); a sagittal water-excitation 3D double-echo steady-state sequence, sagittal T1-weighted spin- echo sequence; moreover a 3D transverse oblique (parallel to the long axis of the femoral neck) water-excitation true fast imaging with steady-state precession (FISP) sequence, used to reconstruct radial reformations for assessing the femoral head-neck junction using the long axis of the femoral neck as a rotation axis. Many experienced surgeons prefer radial proton images with the slices being perpendicular to the femoral neck axis [25].

PATHOLOGIES EXPLORED BY ARTRO-MRI

1. Femoroacetabular Impingement (FAI)

Femoroacetabular impingement of the hip joint (FAI) is increasingly being recognized as one of the causes of hip pain and restriction of hip motion in young adults. FAI refers to abnormal contact between the femur, typically at the junction between the antero-superior femoral head and neck, and the acetabular rim. These repetitive contacts may instigate chondral lesions and labral tears, leading to early degenerative disease [27].

Two main forms of FAI have been described:

- on the femoral head side, or Cam impingement;
- on the acetabular side, or Pincer impingement.

Often there is a combination of both (mixed type), with one type being predominant [28, 29]. FAI is being increasingly acknowledged as a major cause of early ‘primary’ osteoarthritis of the hip [27, 30]. Clinical evidence of femoroacetabular impingement is characterized by anterior inguinal pain and decreased range of motion with flexion, adduction and internal rotation [31].

The arthro MRI constitutes a valid completion diagnostic examination, since it allows to accurately assess the morphology of the labrum, and, moreover, to highlight any injuries. Both types of impingement, being characterized by a “conflict” repeated between the femur and the acetabulum, can determine an altered distribution of the loading forces on acetabular labrum and on adjacent articular hyaline cartilage with consequent possible development of premature hip osteoarthritis.

Radiologist’s task is to help the orthopedic surgeon giving him informations about anatomy, presence and severity of bony contour deformities and of labral and chondral lesions [28].

A. Cam Impingement

In pure cam impingement of the hip, the predominant abnormality is in contour of the anterior/superior femoral head–neck junction, with a normal morphology of the acetabulum.

The symptomatology is characterized by continuous or intermittent hip pain exacerbated by the activity physics: it appears, in fact, during exercise or as soon as it is finished, probably because of repeated microtrauma.

Normally, the anterior/superior femoral head–neck junction has a concave configuration; it appears either flattened or convex in cam type impingement. The femoral head may become quite aspherical due to this altered morphology. This abnormal contact results in damage predominately to the acetabular cartilage, in a rather constant location along the anterosuperior acetabular rim.

Some authors have also used the term “pistol grip deformity” when describing this lesion because of the resulting appearance of the proximal femur on an AP radiograph.

Epiphyseal extension is best seen on coronal MRI sequences as they most closely approximate the AP view of the hip. To measure the sphericity of the femoral head, the alpha angle may be the simplest method to perform clinical setting: necessary tools for measurement are available on most clinical workstations. The alpha angle is measured on an oblique image through the center of the femoral neck. A line is drawn along the long axis of the femoral neck, bisecting a circle which outlines the femoral head. A second line is then drawn from the center of the circle to the point at which the femoral head or neck protrudes ahead beyond the confines of the circle. All patients with impingement have an alpha angle of 55° or greater while those without cam impingement have an alpha angle less than 48°.

Asymmetry of the femoral head–neck junction and neck waist can be appreciated by comparing the anterior to posterior bony contours on radial or sagittal sequences. Although MR arthrography is not necessary to assess the morphologic abnormality of the proximal femur, intraarticular gadolinium helps visualize the cartilage and labral lesions which are often associated with femoroacetabular impingement. The normal acetabular labrum should be low signal on all pulse sequences [32, 33, 34]. The Cam form is commoner in young males in the 3rd decade and the femoral head–neck junction is aspheric [27, 35–37]. Cam associated cartilage lesions are much larger in width (circa 10mm) and focal compared to Pincer chondral lesions, and are also evident in the anterosuperior acetabular quadrant. Increased delamination, associated with acetabular cartilage [35], is present in Cam FAI, where the mean flap size is 7.6 mm, with a range of 2–30 mm [36]. Delamination can be evident as hypointense line in the acetabular cartilage on sagittal FS intermediate-weighted or T1-weighted sequences. Normal ranges of hip cartilage with T2 mapping [27, 38] of asymptomatic adult hip have been defined, confirming cartilage symmetric thickness of the hip joint in all regions. dGEMRIC technique allows to save time using some variations such as only use of delayed gadolinium post-contrast imaging of cartilage [27, 39].

Since most of the lesions are localized on the anterior-upper region, the oblique sagittal and axial scans are those that, with greater precision, allow a correct diagnosis. Radial acquisitions also facilitate complete assessment of the femoral head-neck junction, including the anterosuperior quadrant, where the cam deformity is often most pronounced [40]. During the evaluation of a cam impingement MRI arthrography examination is able to detect early stages of pathology: cystic areas can be identified (“herniation pit”) as focal areas of hyperintensity in the SF sequence. Reactive edema is also evaluated in anterior impingement.

B. Pincer Impingement

The pincer impingement form, either diffuse or focal, is common when a deep acetabular fossa is identified [27, 31]. This anatomic conformation creates an abnormality in the shape of the acetabulum, also known as pincer lesion. When there is overcoverage of the femoral head by the acetabulum, commoner in females in the 4th decade [11], a cross-sectional image through the acetabulum makes it appear like a pincer gripping the femoral head, rather than a cup in which the femoral head rests. Consequently, when a morphologically normal proximal femur is taken to the extremes of physiologically normal flexion in the presence of a pincer lesion, the rim of the acetabulum impinges on the neck of the femur.

MR measurements derived from conventional radiographs, such as the center edge angle, can be used to assess acetabular morphology and to measure acetabular protrusion [41]. In the Pincer form the labrum can be partially or more fully ossified, with variable avulsion. Labral/acetabular junction ossification may be evident at the demarcation zone of bony apposition of the labrum and acetabular rim [27]. Pincer-associated cartilage lesions of anterior and superior acetabular quadrant involve a large, thin (some 4 mm) circumference. There may be an associated posterior or inferior acetabular margin contrecoup lesion [27, 35].

2. Lip Acetabular Injury

The acetabular labrum is a fibrocartilaginous structure that functions as shock absorber, joint lubricator and pressure distributor. Increasing the surface of acetabulum of 28%, it helps to distribute load. This structure is poorly vascularized.

The acetabular rim syndrome (ARS) is characterised by recurrent episodes of sharp groin pain and painful acetabular impingement. It is most often seen in patients with dysplasia of the hip and is increasingly being recognised as cause of their pain [42]. The acetabular labrum shows hypertrophy, degeneration, and/or tears as a result of an abnormal overload. These changes have been identified as early precursors of osteoarthritis of the hip [43]. Improvements in MRI arthrography have given enhanced visualisation of labral integrity allowing better management. According to the most recent techniques of arthroscopic surgery is often required as diagnostic survey because it allows to confirm clinical suspicion and, secondly, to demonstrate site, extent and type of lesion of the lip itself.

Depending on characteristics of the MR signal, the degeneration of acetabular labrum could be classified in varying degrees following Czerney method [44]:

- IA: area of increased signal intensity in the center of acetabular labrum does not extend to the free edge;
- IB: same of degree IA, but with thickened and deformed labrum; absence of recess;
- IIA: the mean of intra-articular contrast is partially in the acetabular labrum fissured, with a regular triangular appearance, without detachment; evidence of recess;
- IIB: as the degree IIA, but with thickened and deformed labrum; absence of recess;
- IIIA: labrum is detached, there is a triangular shape and the recess;
- IIIB: as the degree IIIA, but with thickened and deformed labrum, without recess.

The diagnosis of acetabular labral tear on MR arthrography is established when gadolinium could be seen traversing a portion of the labrum. Radial-sequence imaging improve detection of labral tears: it displays the labrum in cross section around the entire acetabular rim, however not revealing labral tears not visible on standard imaging planes. Standard imaging planes, particularly the oblique axial plane, sufficiently demonstrate all acetabular labral tears.

The vast majority of labral tears occur in the anterosuperior quadrant [45, 46]. Their shape becomes more variable with advancing age. The incidence of triangular labrum decreases markedly with age, but the incidence of rounded and irregular margins increases [3, 9].

The acetabular labrum exhibits variability in shape, symmetry, and MR signal intensity. The most common labral shape is triangular and occurs in 66–69% of asymptomatic hips. Round (11–16%) and flat (9–13%) configurations are less common. A small percentage of patients (3%) do not have a labrum [3, 8]. The labrum varies 2–3 mm in thickness. It is thickest in the superior and posterior aspects and widest in the anterior and superior aspects of the hip [47].

The role of the diagnostic radiologist is to review for features that confirm the diagnosis, to define the extent and severity of labral avulsion and cartilage lesion, to exclude other diagnoses and the presence of advanced osteoarthritis (which is associated with poorer post-surgical outcomes) [3]. Investigators have identified many MRI anatomic variants which can be misunderstood whit labral degeneration, such as several sublabral sulci, perilabral sulcus, transverse ligament–labral junction sulcus, anterosuperior cleft.

3. Labral Tears

This type of lesion can be seen in patients with developmental dysplasia of the hip, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, iliopsoas impingement, repetitive or acute trauma, or osteoarthritis [48, 49].

Figure 1a,b. Fluid collection in peritrochanter bursa at the gluteus tendon insertion. Coronal FSE STIR WI.

Hip MR arthrography has a high accuracy in the detection of labral tears and is the imaging modality of choice in patients with a strong suspicion of labral lesions. These abnormalities include partial tears, complete tears and labral detachment (more common than tears) [50]. A radial imaging provides cross-sectional sections which allow to study labrum and articular joint negating the effects of volume averaging.

Figure 2a,b. Stage I AVN in Coronal FSE T1 and STIR WI. Decrease of signal intensity in T1 images in the subchondral spongiosus bone and increased signal in STIR W images . It refers edema intraspongiosus without necrotic bone area.

Figure 3. Ultrasound guidance for intraarticular puncture and infusion of gadolinium.

Labral tears are usually localized as anterior, posterior or superior. Tears occur most commonly anteriorly. Tears of the posterior or superior labrum are usually seen in younger patients, after a posterior hip dislocation or in patients with hip dysplasia [51, 52].

The Czerny MR arthrographic classification of labral tears has been reported to have an excellent correlation with arthroscopic findings [44].

Figure 4. Drawing shows evolution of chondral defect in FAI pathology. From a minimal incision of the chondral layer to transchondral defect and formation of subchondral geodic changes.

Figure 5. Coronal FSE STIR WI . The labrum and the cartilage are well depicted showing myxoid degeneration in hypertrophic labrum and oblique chondro-labral tear.

Figure 6. Sagittal FSE T1 WI shows subchondral bone area , sclerotic rims and disomogenous signal intrasubstance to refer as subchondral fracture post labral bone impaction in FAI pincer type.

Figure 7. Radial MR image clearly depicts cartilage defect.

Udine, Italy

ABSTRACT

In scientific literature, there are many discussions about the conservative surgery of the joints. In particular, speaking about the hip, all papers suggest that the principal goal is to be able to prevent the degeneration of the joint and the subsequent prosthetic replacement. Pathologies such as femoral-acetabular impingement (FAI), sequels of Perthes's disease or developmental dysplasia of the hip (DDH), are considered precursor of osteoarthritis (OA).

To apply correct concepts of preserving hip surgery is paramount a better understanding of the mechanisms leading to the disease. In addition to the pathophysiology, that leads to particular deformity to be treated, the precise spatial awareness allows to design and to implement the best procedures.

Available surgical options for the hip preservation are arthroscopy, which is assuming increasing importance in recent years, the surgical hip dislocation, which allows optimal viewing of the pathology in question and pelvic osteotomy, able to treat the more serious diseases both in adulthood and in childhood.

A better and comprehensive view and understanding of the pathology is essential to choose the most appropriate surgical option. In last years, several methods that allow to create three-dimensional virtual models were developed: from rudimentary models we come to specific patient models that can replicate the motion, simulating the presence of soft tissue and simulate surgical correction. To create these virtual models a data source is required: literature describes various methods capable to start from patient imaging to returning a 3D model. It is possible obtain 3D images from both MRI and TC or other diagnostic investigation. They are becoming more important those methods can evaluate the range of motion and showing what are the portions of bones (and soft tissue) that come into contact. Collision detection can become an important tool, not only for plan a procedure, but also, for some authors considered that as a diagnostic instrument capable

* Corresponding Author's Email: paolo.dibenedetto@asuiud.sanita.fvg.it.

to distinguish different type of disease. In this chapter, some practical applications are described and are shown the future prospects of improvement of these three-dimensional simulations.

Keywords: hip preserving surgery, virtual model of the hip, 3D, arthroscopy, surgical hip dislocation, osteotomy

INTRODUCTION

Internationals registers of arthroplasty show how the number of hip implants maintain an increasing trend: all years the number of hip replacement raise and that denote the magnitude of problem about hip disease. Orthopaedics surgeons have set themselves a question: the only solution is the hip replacement or it is possible undertake surgical procedures that can prevent the degeneration towards osteoarthritis or at least delay it?

In recent years the modification and development of technique that allow surgical treatment of squeals of different childhood conditions, including developmental dysplasia of the hip, slipped upper femoral epiphysis and Perthes' disease, otherwise treatment in adulthood of chondral lesions, labral tears or femoro-acetabular impingement (FAI) become available [1].

We talk about pelvic osteotomies or intracapsular procedures such surgical hip dislocation and hip arthroscopy. Hip preservation surgery has grown in popularity, and in literature was reported a good to excellent short-term outcome. Despite, for example, the successes of hip arthroscopy in last decade, now we saw that correspond an increase in the number of revision hip arthroscopy and hip preservation surgeries. That kind of surgical procedures require a learning curve and are technically demanding. Traditionally, surgeons have relied on 2D imaging for the asses of joint congruency and morphology. Now, with the evolution of the technology, all major authors describe that a three-dimensional (3D) visualization is necessary to ensure best results favouring an easier and safer approach to this surgery. Instead, total hip replacement (THA) has become an option to consider at a later time and always in patients with a diagnosis of osteoarthritis.

HIP ARTHROSCOPY

Since the description of FAI by Ganz and Leunig [2, 3], an improved interest of hip disease in the young adult has emerged. Afterward, thanks to several studies in non-arthritic hip disease, it is better understood the pathophysiology of hip disease and new pathologies, such sub-spine impingement and ischio-femoral impingement, are recognised and well described. Subsequently hip arthroscopy has become more important for the treatment of these diseases [4].

Now we can consider hip arthroscopy indicated in pathologies at their first stages when this type of treatment can be decisive or when it can be able to delay as much as possible a more invasive treatment.

The hip arthroscopic approach may be considered a challenge: the deepness of the joint and the thickness of the soft tissue around the joint leads to a development of specific

arthroscopic instruments. The awareness of spatial orientation is demanding in hip joint due to its depth in the body, surrounding anatomic and neurovascular structures.

Diseases may affect hip are classified in intra and extra-articular: femoro-acetabular impingement (FAI) is actually the first indication for hip arthroscopy. Femoro-acetabular impingement was described first time in 1936 by Smith-Petersen [5] and it is considered a common cause of non-arthritic hip pain. Femoro-acetabular impingement is the result of the continues collision of the head-neck junction and the upper edge of the acetabulum, particularly with hip into flexion, adduction, and internal rotation. It can be classified in *cam-type* impingement that derive from a bump morphology of femoral neck, *pincer-type*, if impingement derive from acetabular rim over coverage or *mixed-type* when both patterns are present; Other diseases that can be treated by arthroscopy are cartilage injuries whit pathognomonic signs such “wave sign” visible usually in CAM and mixed FAI, osteochondral lesion, infrequent and originates often from traumatic dislocation, labral lesion, frequently source of pain, indeed the labrum is rich in vascularization and innervation.

Unfortunately hip arthroscopy is not free of complications: the most important is the fracture of femoral neck after excessive osteochondroplasty for treat FAI [6] due to a wrong pre-operative planning and a non completed knowledge of the patho-morphology of the hip. With the objective of avoiding the complications and achieve better results are being developed many methods for preoperative planning, virtual simulation and intraoperative navigation.

SURGICAL DISLOCATION OF THE HIP

Surgical dislocation of the hip allows to approach to intra-articular and extra-articular diseases of the hip in adult and paediatric patients. Potential danger to the vascularity of femoral head could be considered as a deterrent but complete visualization of femoral head and acetabulum permits a complete observation of mechanism who lead to pathology and treatment of several diseases of hip. Before Ganz et al. description of a safe procedure to access at hip joint [7] avoiding avascular necrosis of femoral head, rarely is mentioned in treatment other than arthroplasty: only in treatment of rheumatoid synovitis [8], synovial chondromatosis [9], pigmented villonodular synovitis [10] and labral tears [11]. Ganz et al. describe a posterior approach to hip but is not the only one: with anterior approach (Smith-Petersen) dislocation results safely but visualization is limited without detachment of *tensor fascia lata* and *gluteus medius*. Anterolateral and direct lateral approach show have the same visualization problem. Posterior approach allow good visualization with tenomytomy of external rotator muscles; it is possible avoid tenomyotomy preforming a trochanteric osteotomy, as describe in Ganz procedure.

In traumatic dislocation of hip, accident of nutrient vessels of femoral head happen more frequently than in surgical dislocation. In particular posterior traumatic dislocation registered higher rate of avascular necrosis of the femoral head (AVN) [12]. The time of dislocation in surgical procedure is always shorter than six hours, considered the critical limit after that may occur complications [13]. Avascular necrosis of femoral head can occur after surgery and the most useful radiological exam to evaluate femoral head is MRI. However is possible assess the perfusion of femoral head in real time during surgery: laser Doppler flowmetry allow the

intra-operative monitoring [14]. Surgical dislocation of hip require sacrifice of *ligamentum teres*: there are concerns in literature about loss of proprioception since that ligament contain nerve receptors similarly to the anterior cruciate ligament of the knee [15]. Ganz considers possible, in future, preserve *ligamentum teres* and his innervation in many cases, that today require surgical dislocation, with an increase in experience in subluxation of the head procedures [7].

In the end, surgical dislocation of the hip, in expert hands, could be considered a safe procedure useful for many diseases which afflict hip, specially for important deformity and sequels of childhood pathologies.

OSTEOTOMIES

Osteotomies of the pelvis and upper femur serving a useful purpose and long lasting in the general management of post-traumatic and developmental conditions of the hip: are procedures that require a lot of experience by the surgeon.

Femoral Osteotomies

The femoral osteotomies are intended to restore normal anatomy and minimize the risk of evolution in osteoarthritis, but often are associated with pelvic osteotomies. Commonly the target of such surgical procedures is to correct the increased valgus and the increase anteversion in femoral neck: are classified in undertrochanteric, intertrochanteric and trochanteric osteotomies. The first usually are shortening osteotomy with the aim to reduction of femur in case of developmental dysplasia of hip (DHH). The intertrochanteric one is a derotational and varus osteotomy with a cervical-diaphyseal angle of 115°-120° as goal. Trochanteric osteotomies are useful for those cases where an elongation of the femoral neck is necessary but are very difficult procedures and provide great experience of the surgeon to avoid osteonecrosis of femoral head [16].

Pelvis Osteotomies

The aims of pelvic osteotomies are the same as femoral ones: restore a correct anatomy for prevent early joint degeneration. The concept of increasing the coverage of the femoral head allows to increase the acetabular surface subjected to the load. What it makes it challenging pelvic osteotomies is the planning process itself: orientation and shape are factors to be keep in mind. We can classify osteotomies in two big families: reconstruction osteotomies (in turn divided in reorientation and reshaping) and saving osteotomies. Reconstruction procedures are indicated in the absence of chondral damage and in the presence of good joint congruence; reshaping osteotomies are possible only before *cartilago ypsiloformis* is not yet ossified. In contrast, the saving osteotomies are indicated to reduce pain and to delay prosthetic joint replacement [17-20]. A careful preparation, done through knowledge and planning of the procedure to be performed is essential for an optimal result.

VIRTUAL JOINTS MODEL

The biomechanical study of joints during various human activities, through virtual anatomical joints models, can be considered an advantage in many field of medical and orthopaedic research. The main goal leading the orthopaedic surgeon researching in this field is the get "tools" that will improve the results of surgical procedures required for each patient and decreasing complications.

To obtain a virtual joint model we have to start from biomechanics. David Winter, in his book [21], defines biomechanics as an interdisciplinary field that describes, analyses, and assesses human movement: so we can say that biomechanics study human function through a mechanical point of view.

Consequently, biomechanics needs some concepts of physics to be understood: *Statics* studies bodies (bones for example) in state of equilibrium, when transitional and rotational movement are zero. *Dynamics* investigates how forces and torques determinate a movement of bodies or alternatively, in case of impediment to move, bodies undergoes *Deformation*. Therefore, intrinsic proprieties of material under studying are important [22].

Others two important concepts are *Elasticity* and *Plasticity*: the first one is defined such the capability of a material to restore his original shape after the application of load (force) that has deformed it. The second one described the behaviour of a material that have overcome the *elastic limit* and cannot restore his shape and deformation will be considered permanent.

The above concepts are the basis for the studies necessary for the creation of virtual models and subsequent simulations: in particular, *Statics* and *Dynamics* can explain what are the joint loads and what the possible movements depending on the forces involved and as the movements, to be analysed, are not pure movements, but compounds from simpler movements associated. Since the range of joint motion is limited physiologically, when you at the stroke end the surfaces of the bone segments collide: in this case play an important role the deformation, the elasticity and plasticity. An ideal virtual model should take into account the different characteristics of the tissues involved and the different deformation capacity and, in a sense, consider the real joint behaviour. These characteristics lead to an increase of the amount of data that must be analysed by specific software [23] and then, often, the simulations must be simplified in order to work in real time, as be seen, for example, in the work of Wilhelms [24] which introduced a method where the skeleton is simplified to a tree of three concatenated ellipses that represent the bones.

Data Origin

If the virtual models are used to plan surgical procedures, we have to keep in mind the subjective anatomical variation between different patients we are going to study: customization of patient's joint model are to be useful for surgeons. A generic simulation may be useful in understanding the pathogenesis but could be used in clinical practice. Individualized musculoskeletal model is the right way [25].

(a)

(b)

Figure 1a,b. A CT-scan of a 24 years old man with multiple exostoses disease.

But what are the sources of data to be searched to get personalized virtual models? Medical imaging techniques are the answer such Radiographic examination, Computed Tomography (CT), Magnetic Resonance Imaging (MRI), Positron Emission Tomography. All of these techniques can be source of data to generate 3D model to study relationship through bones and other structures; but a critical step is necessary: the segmentation. The imaging

segmentation is the procedure to extract information from medical 2D images to create an anatomical 3D structure: all tissues represented in the image should be recognized and should be separated. The difficulty lies in the fact that the bone is not uniform due to the presence of vessels, fat, connective. Exist software able to do that automatically but often it is necessary do that manually [26] for better results. After have obtained segmented data from patient's scans need further processing to produce virtual model through specific algorithms and software [27, 28]. Another step is gain and the hypothetical 3D joint model it is available, but the model cannot simulate the real human joint without the acquisition of data related to kinematics.

Collision Detection

Starting from a human hip joint 3D model, built by reconstructing three dimensional meshes of joint's tissues (cartilage, bone) and estimating hip rotational centre, another target is the detection of colliding areas between during motion and the precise evaluation of specific range of motion (ROM). Many methods are available for detect collision but most of these are not specific and in particular result very expensive in computation time, then less useful in high speed evaluation such in hip joint range of motion analysis. Important element, in addition to collision detection, are the penetration depths (radial or cylindrical) [29].

Faster and easier methods are paramount for medical hip simulation and can lead to real time evaluation. Furthermore depth penetration assessment can give diagnostic information and would be considered helpful to define treatment [30].

Colliding areas define specific range of motion about that particular hip underwent to analysis: extrapolated information from range of motion, such for example limited internal rotation, could be important findings for a better diagnosis of hip disease [31].

Movements of hip joint can be simplified in two elementary motions: sliding and rotation. Both imply two possible collisions such sliding one and striking one. Different methods of segmentation can better analysed particular collision.

For improve collision detection from pure rotational motion a cylindrical segmentation is needed: the space around the rotatory element is divided in concentric cylinders and then in concentric ring-shaped segment, comprising also fixed element. Hence, when the element during his motion penetrate a segment that correspond to a portion of fixed element is registered. Computational analysis of all registration lead to detection and localization of collision between two elements. Indeed, for detection of collision from sliding motion is more useful another type of segmentation: radial segmentation of space. Starting from a rotational centre, the space is divided by tracing rays from the centre of rotation. The angles between two half-lines are under analysis: if the vertices of the element in motion penetrate the static element, the depth of the intersection between the elements is registered. The analysis of all position of colliding vertex allows to calculate the ROM [29].

From these concepts Arbabi et al. [30] develop a method of real time collision detection for medical evaluation of hip that discern for pincer-type and cam-type Femoral-acetabular impingement. Curvilinear penetration in pincer-type is study by cylindrical segmentation and cam-type by radial segmentation.

(a)

(b)

Figure 2a,b. 3D CT-scan and collision model reconstruction showing the exostoses on the femur colliding with the acetabulum.

Concepts mentioned above demonstrate how collision detection and ROM assessment could have implication in medical assessment and treatment of several diseases that afflicts hip joint.

VIRTUAL MODEL APPLIED IN FEMORAL-ACETABULAR IMPINGEMENT (FAI)

FAI treatment is the principal indication for hip arthroscopy procedures but not the only: specific deformity, who characterized cam or pincer-type FAI, is assessed through precise clinical manoeuvres and radiographic findings. The most relevant are, respectively, the alpha angle of Nötzli *et al.*, defined as the angle between the femoral neck axis and the line connecting the centre of the femoral head to the point of femoral head asphericity [32] and the centre-edge (CE) angle of Wiberg, another one important finding, formed by a line drawn perpendicular to a baseline that passes through the centre of the femoral heads and a line connecting the centre of the femoral head and the superior border of the acetabulum [33].

Many authors have concluded that the alpha angle single measurement must be considered in critical manner. It is demonstrated that often the alpha angle measured on radiographs does not coincide with the size of the deformity found intraoperatively. A measurement on 3D images allows to determine the size and the position of the CAM deformity respect to the head-neck junction of the femur and allow better planning and surgery treatment [34]. The same applies to the pincer-type FAI deformity: 3D images allow better bony acetabulum coverage assessment [34].

Treatment of femoral-acetabular impingement can be performed through arthroscopic approach or open approach with surgical dislocation of hip; the two procedure seem have comparable outcome [35]. Complication of these kind of joint preserving surgery of the hip (JPSH) have a low rate of complication in many studies (1,9% for arthroscopy; 4,1% for surgical dislocation of hip) [36]. The choice of what surgical procedure undertake should be guided by the complexity of the disease at issue: surgical hip dislocation may be the best treatment in severe deformity or in every cases is needed a comprehensive deformity correction. In particular severe deformities on acetabular side are demanding by arthroscopy [37]. All others cases can be treated, in security, with hip arthroscopy.

Complications about hip Arthroscopy can be several and all due to particular factor such the deepness location of the hip joint, nearness of neurovascular structures at risk for injury, the poor visualization caused by the constrained osseous geometry of the joint, the limited working space caused by strong capsule. All these reasons may lead the surgeon to under-resection or over-resection the bony deformity, most frequent arthroscopy complications.

The above discussion lead to the necessity of tools to make the best approach to the hip for the arthroscopist in order to facilitate the treatment and decrease the complications: to do that a virtual and simulated approach may be the way.

Several software are available for virtual models obtained by imaging investigations; only few of these need “coordinate” to orientate positions of any bone. Through segmentation, bony landmark are identified and specific algorithms can simulate ROM and identify location of impingement better than 2D images [38].

More accurate software are able to locate and measure the deformity better thanks to a rotation centre of the hip that simulates not only the rotation but also the translatory motion (as occurs in the hip human) [39].

A virtual model of the hip able to consider the deformability of the involved tissues and able to evaluate the type of deformity in real time can become a useful tool, not only for the pre-operative assessment but perhaps also a diagnostic tool capable of even directing the next

treatment. Arbabi et al. in his work [30] developed a computer-assisted method for real time evaluation of hip disease based on assessment of penetration depth of colliding tissues; in particular, he demonstrates the ability of that system to determine difference in penetration depth between cam, pincer, mixed-type of FAI and hip dysplasia. Starting from a normal hip (defined in his study a hip with alpha angle about 40° and CE angle about 20°) his group analysed 25 hip model with all possible combination of above parameters during full range of standing-to-sitting movement [40]. Therefore all possible kind of disease were assessed during standing-to-sitting motion and results that each of 25 hip model correspond to a specific pattern of penetration depth. Dysplastic and normal hips could have a normal range of motion, on the contrary mixed-type of FAI could show lesser range of motion.

(b)

(c)

Figure 4a,b,c. The case of a 24 years old man with the multiple exostoses disease treated with hip arthroscopy by the author according to collision model indications. The preoperative x-ray (a), the post-operative x-ray (b,c).

From preoperative evaluation of 3D images, to simulation of the range of motion and the collision detection to assess hip before and after surgery. The next step is assistance during the surgical procedure: computer-assisted surgery (CAS) applied to joint preserving surgery of the hip (JPSH) allow gaining additional advantages: know the tool position during surgery help to perform better the procedure. A particular system could synchronize intraoperative and perioperative imaging. Surgeon can verify real time, during surgery, to make better and more accurate corrections of the deformation in issue [41]. Furthermore, to the position of instruments, generation of simulated fluoroscopic images from 3D models can be useful to compare with intraoperative fluoroscopy imaging to verify that have properly executed the planned correction in all positions you want to assess [42].

VIRTUAL MODEL APPLIED IN DEVELOPMENTAL DYSPLASIA OF THE HIP (DDH)

Today is possible to ensure a better execution of surgical procedure, thank to the advance in technology that allow 3D preoperative plan and 3D simulation. As we saw earlier, source of data can be multiple: CT, MRI and more. In this section will be exposed a CT-based preoperative and intraoperative navigation system [43]. For hip osteotomy, it start from CT data processed by a specific software to obtain three-dimensional template; another specific modelling software prepare the preoperative surgical plan and then it is transferred to a 3D navigation system.

If a rotational osteotomy [44] is to be performed, we have to find specific points on medical images to plan the osteotomy: first the centre of hip joint that will be the centre of a sphere, with a diameter often between 80-90 mm, that will indicate limits where perform osteotomies.

When osteotomy is plan, simulation of rotational correction of osteotomy can be performed: the fragment is laterally rotated to achieve correct acetabular roof obliquity angle [45] and anteriorly rotated to obtain correct coverage. A similar preoperative plan is also prepared for femoral osteotomies such varus, derotation and rotational of the head. It is also possible simulate the placement of fixation device after correction. If, after simulation, some impingement site was find by colliding software analysis, it is possible plan specific osteochondrolplasty procedure.

Intraoperative assistance of 3D navigation system is paramount: tip of trackable curved chisel is always identifiable on computer and it is important when visualization is poor such in pubic osteotomy. Visual and audible alert advise the surgeon when procedure is not following the plan.

When the osteotomies were performed, it is possible examine the results through specific trackable probe before fixation of fragments. In the same manner, we can achieve femoral osteotomy.

Advantage of this example of virtual model simulation use seem are capability to perform safe osteotomy always under computer control, even in poor visualization condition and a reduction of x-ray intraoperative exposure. However, disadvantage seem are longer operative time and preoperative radiation exposure (CT). It can nevertheless be concluded that the use of these techniques is an advantage for patients, as also reported in the literature [46].

DISCUSSION

Costs

In above paragraphs is described how virtual model can lead to a better knowledge of disease that afflict hip. Usual radiographic assessment such MRI or CT study may be consider useful for diagnosis but, especially when subjective symptoms are not specific, can demonstrate low cost-effectiveness. In Kenney et al. work use of MRI as diagnostic tool is analysed [47] and results show a substantial difference between cost-effectiveness in relation to kind of symptoms pattern are being investigated. That retrospective study proves how little a hip MRI, done to investigate hip pain, influence the treatment.

Is also examine the cost-effectiveness of MRI and the results suggest “that MRI is a poor tool when used in the assessment of patients presenting with pain without a strong clinical suspicion for a specific diagnosis” and “is not cost-effective as a screening tool for hip pain” [47]. Another study conducts by Kahlemberg et al. concluded that the cost per patient for obtain diagnosis of femoral-acetabular impingement is 1500 \$ higher than calculated minimum cost [48].

Maybe the cost-effectiveness of virtual model, built starting to MRI (or other radiographic study such CT), could be better: if it has been demonstrated the superiority of virtual models in providing information to identify the correct diagnosis and determine the best treatment possible, the cost-benefit analysis should be encouraging. On the other hand, there is a lack of studies in literature that verify the above data, even if the hypothesis seems plausible.

From Virtual to Real

There are particular cases in which the three-dimensional virtual model is not enough. Objective difficulty of some surgical procedure such peri-acetabular osteotomy (PAO) demonstrates the necessity of an accurate pre-operative planning. A 3D virtual simulation is a great help, but especially for the pelvis, may prove difficult to perfect spatial orientation and awareness of three-dimensionality. How to work around this problem?

The rapid prototyping (RP) can be the answer: it is defined as a set of techniques to achieve physical models useful for features verification of a model. The target is to create a prototype of the bone component to be corrected which faithfully reproduces the size and shape and which is possible to handle. Rapid prototyping is a procedure composed by three fundamentals steps. The first is the creation of a “*Standard Triangulation Language to Layer*” file (STL): in the medical field, the STL file is get from the usual radiological investigations such as MRI or CT scan. The second step involves the STL file verification and preparation before the actual construction of the prototype. The third step consists in the construction of the prototype layer by layer. The deposition of material can occur by different ways; one of these is the “*Fused Deposition Modelling*” (FDM). Ratnadurai D. et al. [49], in his work, speak about the FDM as a method useful, rapid to realize prototype which can be sterilized by gamma radiation and therefore potentially handle able during surgery; also the material with which it is made has characteristics similar to bone. Always from Ratnadurai’s work “*in DH*

surgeries, the benefit of using FDM models include helping the orthopaedic surgeons to make decisions in reduction of the hip in acetabular reconstruction, accurate placing of bone grafting, femoral shortening and to determine the suitable implant sizes for the patients.” Also Tong K. et al. [50] use template in treatment of DHH for pre-operative and even for post-operative assessment of correction. Tong declares that it is an advantage in peri-acetabular osteotomies have a physical model. In addition, in the field there is a lot of development; It is desirable in the future to have the resources to be able to accomplish on your own and in time of need this type of models.

CONCLUSION

Preserving surgery of the hip joint is experiencing a period of growth under the pressure of new procedures that address in a less invasive with better consciousness of many diseases that would inevitably lead to osteoarthritis (OA), sometimes precociously. Treatment options may be different but target of the intervention remain the same: restoration and conservation of the hip joint function and pain alleviation. Various diseases that lead to osteoarthritis can be treated with different expectations of outcome, dependent on the severity and complexity of the case. Virtual models of the hip, above described, allow a wider knowledge of the deformity and therefore a more accurate diagnosis, better preoperative planning, even a more secure execution of the surgical procedure and a careful post-operative evaluation. Future steps, for orthopaedic surgeons, will be to make easier accessibility to this type of investigations and assessments. This will be possible if the efforts for the development of these technologies will be to simplify the various surgeries. In addition, in the future it would be useful to allow the surgeon to be able to manipulate the data obtained from the patient images individually and to be able to reconstruct the virtual models directly in the operating room to assess the effective correction of the defect and restoring the proper joint biomechanics.

Chapter 150

THE LIMITS AND FUTURE OF COLLISION MODELS

ABSTRACT

Introduction of collision models aided surgeons to plan their resection of the femoral and acetabular impinging deformities. Their application on the hip joint is particularly interesting in association with hip arthroscopy because with technique the vision is limited and identifying friction's zones is not easy. Although their large diffusion in the market, they still presents several limits. First, the 3D reconstruction has been used only in the preoperative phase. Its use inside the operating room is still not available. Furthermore the actual software lack of a pure automatized program to create the 3D model of the hip. Second, nowadays collision model's software separate and study only the bony part of the hip, erasing from the 3D reconstruction soft tissues. Third, the programs currently developed use statistical data as reference to 3d virtual models and the motion between the hip's bones. They base the motion analysis on the comparison between data extrapolated from the healthy population and data from the patient exam, consequently image processing may be inaccurate. Although according to our opinion collision model are useful even with their actual limits, in this chapter we describe the limits of the actual software and their potential development.

BACKGROUND

Femoroacetabular impingement (FAI) is a recognized leading pathomechanism contributing to a hip arthritis. Actually, FAI individuation is usually based on clinical exam, xrays, MRI or CT scans. All these exams suggest the diagnosis of FAI but they are not able to show the impinging areas. With this preoperative imaging studies, the success rate of hip

* Corresponding Author's Email: ale_aprato@hotmail.com; Fax: +39 338 6880640.

arthroscopy is reported between 67%-80% [1] and most of the surgical revisions are performed for inaccurate bone resection [2-4]. In order to improve these results, 3D reconstruction services using collision models [5] have been presented in the market (i.e., “Clinical Graphics” and the “Dyonics Plan”); those programs can localize regions of anticipated mechanical impingement in patients with hip pain aiding the surgeons to plan the bone resection.

Even if collision models were created to improve the precision of bone resection, poor scientific evidence is available at the moment. Bedi [6] used collision models either before either after arthroscopy surgery and showed an improvement of hip range of motion (ROM) after resection of the area defined as impinging by the models, unfortunately the post-operative pain was not considered as an endpoint. Unluckily, up to date it's still not available a study comparing the success of the hip arthroscopy using or not preoperative 3d models, so their use is recommended only in revision planning, where they proved a good efficacy [7]. Furthermore actual collision models are thought to reduce the actual complex learning curve for this kind of surgery [8], although no study support this statement.

Even with this poor evidence, according to our opinion, collision model are useful in FAI surgery planning. Unfortunately, some unresolved issues and problems due to current limitations of the programs restrict their diffusion on a large scale. The simplification of the processed images compared to the in vivo situation and the lack of intraoperative applications are the major limits. In this chapter we describe these limits and the potential developments of the actual software.

Analysis Issues

Nowadays collision model's software separate and study only the bony part of the hip, erasing from the 3D reconstruction soft tissues; but those tissues have a relevant role in the development of femoroacetabular impingement (FAI) and even in its physiopathology after development.

Figure 1. An intraoperative image of a cam deformity showing the cartilaginous layer (arrows) that cover the bump at femoral-neck junction. FH = femoral head.

Three kind of tissues erased from the reconstruction are important in FAI treatment: cartilaginous tissue, the fat pad [9] and the inflammatory reactive tissue.

The cam deformity is often covered by cartilaginous tissue (Figure 1): its thickness varies individually [10] and may anticipate the contact between femur and acetabulum. As a consequence, erasing this tissue from the reconstruction may underestimate the FAI.

Although rare, a fat pad found at the anterior head/neck junction of the hip joint may be the cause of the femoacetabular impingement (Figure 2-3). The fat pad may be due to repeated traumas by the labrum and acetabular margin during the impingement process [9].

Inflammatory reactive tissues (Figure 4) plays a central role in most of hip disease increasing the inflammatory response and boosting the cartilaginous and bone tissue destruction; during the operations it must be extensively removed.

Figure 2. MRI coronal image showing a soft tissue cam-like lesion (arrows) at femoral-neck junction.

Figure 3. An intraoperative image of a soft tissue cam (fat pad) at femoral-neck junction. FH = femoral head, A = acetabulum, FP = fat pad.

Figure 4. MRI coronal image showing an impinging inflammatory tissue (arrows) at femoral-neck junction.

Algorithm Based Issues

The actual programs use statistical data as reference to develop 3D images and the motion between the hip's bones. They base the motion analysis on the comparison between data extrapolated from the healthy population and data from the patient exam. Therefore image processing may be inaccurate: bones' surfaces are processed not considering only the individual DICOM files themselves but comparing the results of data processing with a library of 3D images from other people. Errors or artifact are manually corrected after the elaboration of the data, this process makes the 3D reconstruction more coherent and requires less specific software but loses accuracy.

Eventually motion simulation may be inaccurate: healthy population presents wide physiologic differences on how the articular faces moves between each other: applying to all these different patients the same algorithm may over or underestimate the FAI; in order to partially resolve this problem new 3D models can use a dynamic center of rotation for the femur instead of a static one [11] [12].

Other Issues

Another important limit of the actual collision models is their preoperative nature: interesting preoperative data are given to the surgeons but without intraoperative data the surgeon should base their correction on their experience and intraoperative tests without a feedback from the software. The use of the collision model inside the operatory field will help the surgeons to avoid over or under-correction. Until now 3D reconstruction of the hip is limited to the preoperative analysis because of the necessity of high definition image in order to render the DICOM file. Therefore it's limited to files taken from TC or MRI scans, which are not present in the operating room.

Furthermore the actual software lack of a pure automatized program to create the 3D model of the hip and this is another reason why they may not be used in real time during surgery. The need of a skilled technician to elaborate the data is another major limit of the actual solutions.

Future of Collision Model

Although according to our opinion collision model are useful even with their actual limits, we think some improvements may transform them in a perfect tool for the surgeons.

Soft tissue related issues can be partially resolved introducing in the future models different kind of tissue, i.e., density has already been used in finite elements analysis to discriminate cancellous from cortical bone [13]. This improvement may complicate the model and its reconstruction phases but it may be very helpful.

Algorithm related issues may be improved by introducing more variables in the algorithm but, according to our opinion, new software need to focus on the DICOM files in order to visualize images less approximated and as close as possible to the real situations. In order to obtain those results, the programs need to analyze more efficiently the DICOM files and not rely on previously acquired images.

By now, the 3D reconstructions are based on DICOM files of TC or MRI which are not available in the operatory room. According to our point of view, there are two possible ways to solve this problem:

- 1- *Intraoperative TC OR MRI*: the continuous development of MRI and CT scans is creating machines that are always smaller and require less time in order to capture the images. In the last five years, few companies created CT scans that are suitable for the operating room (i.e., AIRO from Brainlab [14]). These CT scans are especially suited for spine surgery and they have already proved to improve outcomes [15]. Up to date these machines are not available in most hospitals, are expensive and are not primarily designed for hip surgery; they also require a specially designed operating room and skilled technicians.
- 2- *3D Fluoroscopy*: the 3D fluoroscopy already proved to obtain reliable intraoperative images for cam-type femoroacetabular impingement (FAI) [16] and compared to the intraoperative CT provides an alternative which is less expensive, requires less skilled technicians and can run inside normal operating room without implementing security measures. Even though the main problem with the fluoroscopy stands in the image quality. The latter is lower than TC\MRI's image quality and it represents a bigger challenge for the 3D reconstruction. This issue may be solved either by maximizing the image quality through accurate filter either by creating specific 3D reconstruction's program for fluoroscopy.

To make possible the use of the collision model inside the operatory field the 3d reconstruction programs need to provide the 3D images in real time or in the shortest amount of time possible in order to not prolong too much the duration of the operation. To achieve this goal, the programs should be fully automatized or semi-automatized and the intraoperative data acquisition and analysis should be as easy as possible.

In conclusion we think the actual collision model represent a good solution for preoperative FAI analysis but a new generation of collision model, based on the suggestions we presented in this chapter, will radically reduce the intraoperative difficulties in FAI treatment.

ABSTRACT

The progress of technology, particularly of Additive Manufacturing, has made possible the creation and the subsequent use of custom made 3D devices in hip surgery. These customized devices may be implantable (cup or stem) or non-implantable (diagnostic models, simulation models, cutting templates). The commonly used additive manufacturing technologies are: FDM (Fusion Deposition Modeling), SLS (Selective Laser Sintering), EBM (Electron Beam Melting). Each of these is used for specific purposes and has advantages and disadvantages.

Several surgical techniques have been described to face most of the hip arthroplasties without the need for custom made devices. However, in complex cases, their use may be useful. 3D models allow surgeons to reach a more accurate diagnosis or to simulate surgery. Thanks to the cutting guides tailored on individual anatomy, surgery may be assisted and simplified, reducing operating times, simplifying the critical steps, decreasing the intra and perioperative risks. In selected complex cases, the use of custom made stems or cups may also lengthen system's life and improve the clinical outcome. High costs and long time required for the production of customized products are the major limit of this technique in primary arthroplasty, although in selected complex cases, their use is advocated by the surgeons.

Keywords: hip arthroplasty, custom implants, 3D models, arthroplasty planning, 3D printing

INTRODUCTION

Total hip arthroplasty (THA) is widely considered among the most successful surgical procedures in modern surgery. Modifications of techniques and implant materials over the past four decades have improved the longevity of THA and led to excellent results in most patients. Currently, an estimated 2.55 million individuals in the United States are living with a THA, and the number of THA procedures worldwide is taught to increase in the coming decades [1-4].

Over the years, surgical techniques have been improved and materials have been optimized in order to become more compatible and durable.

In this rapid mutable scenario, realisation and use of custom implants gain popularity in the last five years. An attempt to achieve this target was already carried out in the 90s with the use of custom made prostheses, even in first standard implants. They were based on studies of the morphology of the femoral canal and the acetabular cavity and they were produced according to each patient's features. The practice of custom made in first implants has been put aside because of the current wide possibility of choosing the most suitable implant among multiple alternatives [5-7].

However, to date, custom made prostheses are frequently used in complex primary hip arthroplasty with serious diseases of hip joint, where there are major anatomical deformities or bone losses. Congenital hip dysplasia, trauma, tumors, arthritis in Legg Calvé Perthes disease or Paget's disease are the most common causes of major deformities [8-10].

In recent years, the 3D technology is progressing very quickly and custom made solutions have greatly expanded. In fact, 3D reconstructions may be used not only to produce customized prosthetic implants, but also for diagnostic purposes, for a more precise and accurate planning of surgery, to create specific devices that guide and assist the surgical procedure itself.

Technological advancements of Additive Manufacturing (AM) and its application in surgery has been the key to develop customized models. The term 'Additive Manufacturing (AM),' also called 'Layer Manufacturing,' refers to all those technologies that allow building three-dimensional physical models of an object by adding material layer by layer.

Additive construction technologies allow realizing any prototype in a shorter time than traditional processing techniques. 3D printing was born in 1986 thanks to Chuck Hull who invents stereolithography (Stereolithographic Apparatus). Since the invention of stereolithography, additive manufacturing evolved. The development of several new materials and new technologies has extended the fields of application. The rapid prototyping processes can be classified according to layers printing. Today, in orthopaedic surgery, three methods are commonly used: FDM (fusion Deposition Modeling), SLS (Selective Laser Sintering) and EBM (Electron Beam Melting). Each one has advantages and disadvantages and their suitability depends on the aim of the model. Custom made devices may be classified into two broad categories: implantable and non-implantable.

Implantable stem and/or cup may be created and tailored according to the specific individual anatomy of the patient. The implantable components are created with SLS or EBM technologies with titanium/trabecular titanium biocompatible materials.

Not implantable model are pre- or intra-operatively used to plan or to perform specific surgical steps. They may be grouped into:

- diagnostic models, realized with FDM or SLS technology
- models for surgery simulation, made with FDM technology
- patient-specific cutting masks created with SLS or FDM technology

MATERIALS AND METHODS OF 3D PRINTING FOR HIP SURGERY

3D printing is based on a three-dimensional reconstruction of diagnostic images. CT and MRI are commonly used for this purpose because volumetric three-dimensional images can be easily reconstructed from their data. Quality and resolution of the starting diagnostic imaging are essential characteristics to achieve a precise 3D model. Therefore, acquisition protocols should be standardized to avoid low quality reconstruction. Starting from the Dicom format images, segmentation of the anatomic parts is performed. Several software (i.e., Materialise MIMICS Innovation Suite, ITK Snap, 3Dslicer, 3Ddoctor, VMTKLab) have been commercialized for this aim. Regardless of the software, the basic concept of segmentation is always the same. Segmentation is based upon subdivision of voxels into groups. A voxel (volumetric pixel or, more precisely, volumetric picture element) is a volume element representing a signal or colour intensity value in a three-dimensional space, as well as a pixel represents a data in a two-dimensional image. Voxels can be often used to display and analyse scientific data. The value of a voxel can represent various properties. In a computed axial tomography scan, values are Hounsfield units, indicating the material opacity to X rays. In a magnetic resonance imaging or in an ultrasonography different values are acquired. In a first step, these groups of voxels are subdivided by means of an operation called Thresholding, in which the operator defines two threshold values, a minimum and a maximum values, in Hounsfield units, isolating and gathering all the voxels containing Hounsfield values included in this range. Once gathered, voxels shall be edited in order to isolate the various anatomical structures and/or to correct details in the first thresholding step. This step is delicate, in particular for reconstructions concerning the revision cases, for the artefacts, due to prosthetic material and present on CT/MRI images, are going to be deleted, in order to reconstruct images deprived of significant distortions. Artefacts are a serious problem, which affects every segmentation software and can be only lessened. Therefore, it is important to find the most suitable image acquisition protocol, so that images show already a lessening of artefacts and are filtered directly by the machine during the reconstruction step. Once the anatomic structures have been identified, the software permits to calculate a three-dimensional mesh geometry, starting from the previously isolated voxel groups. This mesh can be then exported in various digital formats in order to be interfaced with another software for 3D printing, engineering design or rendering and virtual animation, according to the purpose. Then, the implant or device design starts. According to the doctor's requests, the technician starts a design procedure. This procedure can be aimed at obtaining a prosthetic implant, a surgical guide or a diagnostic device. Once the design step has been completed, if the surgeon's requests have been met, the device production step is started.

According to the specific applications, the most suitable additive manufacturing technology should be chosen. The constant development of new materials permits a wide

choice for each technology, from soft to stiff material, from coloured to biocompatible material.

FDM (FUSED DEPOSITION MODELLING)

This technology is surely the simplest one among all the fast prototyping methods. The process consists in the extrusion and deposition of molten plastic material. The process is repeated until the model is complete. It permits to realize objects with very complex geometries and high mechanical resistance, to the detriment of longer printing times if compared to other technologies. As concerns the 3D FDM printing materials, they are usually thermosetting plastics. The material usually used to carry out three-dimensional models of anatomic parts for diagnostic purposes is polylactic acid (PLA), which can be used more easily than other materials, for its operating temperature is low (200°C approx.). It is available in various colours and it can be opaque or transparent. It is resistant and has excellent mechanical properties, while the final model can be worked easily and reproduces the bone consistency. Many times, PLA is used in combination with polyvinyl alcohol (PVA) for, thanks to the property of being diluted in water, it is used as base material. For the realization of cutting guides, on the contrary, a material with excellent mechanical properties is required, able to resist to possible strong stresses, biocompatible and sterilizable. Nylon 680 and Nylon PA 2200 meet these requirements, even if they can be printed less easily.

Advantages:

- Cheap
- Sterilizable (Nylon)
- Multicolour, if different anatomic structures has to be highlighted (PLA)

Disadvantages:

- Accuracy and definition (0.25-0.5mm) are not high.
- Printing realization time, according to complexity, of tens of hours, therefore not applicable in emergency surgery. If speed is increased, the possibility of error grows.
- Undercuts: they are suspended (or almost hanging in space) zones of the object and the machine can't print them because, without an underlying support, the melted extruded thread would fall. Normally, an undercut up to 45° can be managed, even if some surface imperfection could be got. If the undercut is higher than 45°, some support element must be added (PVA).

Indications: creation of anatomic models useful for planning or surgical simulation. The particular advantage of PLA models is their possibility of simulating the bone consistency: they can be realized with a harder surface part, similar to the cortical substance, and a deep trabecular part, similar to the cancellous bone. If soluble supports are required for the correct realization of models with particularly complex geometry, PVA may be used. Biocompatible

and sterilizable custom-made cut masks or surgical supports may be also created with this technique.

SLS (SELECTIVE LASER SINTERING)

A layer of thin powder, which can be thermoplastic polymer, metal, ceramic element, is applied and rolled with care, so as to create an even surface. The laser hits the geometry section point to point, layer after layer, providing the heat required to carry out the fusion or the sintering of the material. The powder grains, when hit, create the profile of the section defined by slicing, while the exceeding powder is recovered and used for the next layer. Then, the model is extracted from the powder bed and cleaned. Particular post-production working, such as sand blasting, wax infiltration or painting with epoxy resin, is required to eliminate surface porosity.

Advantages: high accuracy and resolution (0.05-0.15mm), sterilizable, no supports

Disadvantages: higher cost than FDM

Indications: cutting masks, anatomic models, custom-made prosthesis.

EBM (ELECTRON BEAM MELTING)

By fusion, a laser electron beam permits to produce objects starting from an empty space at high temperature. Very thick parts with high mechanical properties may be created with this technique. Titanium and chrome cobalt materials can be used. This technology permits to obtain trabecular titanium components, an innovating multi-planar structure that imitates the porous structure of the cancellous bone and is able to facilitate and stimulate the periprosthetic bone growth.

Advantages: extreme accuracy, trabecular titanium

Disadvantages: high cost

Indications: production of custom-made prosthetic components

NOT IMPLANTABLE CUSTOMIZING 3D

1. 3D Diagnostic Model

In literature, preoperative planning of THA is strongly suggested to minimize surgical issues [11, 12]. Planning involves a complete x ray exam of the hip (anteroposterior pelvic view and lateral view of the hip). Full leg x rays may be indicated to evaluate leg length discrepancy. Eventually a computerised tomography (CT) of the pelvis, femur and femoral condyles is often performed. 3D application may increase the accuracy of the plan: reconstruction of hip geometry provides further data about acetabular and femoral anatomy, including femoral neck version, centre of rotation, offset, femoral helitortion and transition

zone between cortical and cancellous bone. From CT scan data, production of the custom-made device (acetabular cup, femoral stem, 3D diagnostic models, osteotomy guides) may be started. Actual technology permits to reproduce accurate anatomic models. Those models may be really helpful in preoperative planning because the physical, and not only digital 3D model is at surgeon's disposal. The surgeon himself may study all the variables (i.e., assess the closeness of anatomic structures to the surgical site, decide the femoral osteotomy level with precision). Models can be created by subtraction, eliminating excess elements and isolating the ones essential for the surgical procedure. Moreover, as already said above, 3D PLA models simulate both the cortical and cancellous bone consistency in a satisfactory way allowing real surgical simulations.

Figure 1. Imaging 3d reconstruction and diagnostic model.

Complexity of the anatomic deformity is not the only indication for 3D models, the simultaneous presence of surgical critical aspects, such as proximity of anatomic structures may require a preoperative evaluation with 3D models. In Figure 1, an illustrative example regards a serious dysplasia with huge front heterotopic ossifications, with subanklylosis of the same hip is presented. The heterotopic ossification is very close to the femoral artery. In this specific case, the 3D model, in 1:1 scale, beyond being useful for the creation of cutting masks, was essential in order to assess the distance between femoral head and femoral artery.

Figure 2. 3D virtual model of an acetabular fracture based on CT scan images.

3D models may also be used to evaluate the correct cup positioning in complex acetabular fractures treated with acute THA. In those cases, the reduction and synthesis of the fracture is followed by the implantation of a one-stage hip prosthesis. The 3D model permits to get a more complete view of the fracture (Figure 2-3), to optimize the surgical reduction and plate positioning and to choose the perfect position of the cup.

Figure 3. 3D solid model compared with 3D virtual model.

2. Sterile 3D Models

Once the diagnostic models have been created and sterilized, in selected cases, they may be useful to simulate surgery.

Figure 4. Sterile preoperative simulation of posterior wall synthesis.

An example of this application is the reduction and fixation of an acetabular fracture. Reduction may be performed on the 3D model and plates may be bend on it. This may be performed on a sterile tray before incision in order to avoid intraoperative plate bending and to decrease surgical time (Figure 4).

Furthermore sterile 3D models may be used to help the surgeon intraoperatively to choose correct screw direction in complex cases. Direction of the cup's screws may be tried. Eventually, sterile 3D models are useful in acetabular fracture, to practically check the interference between plate screws and cup screws.

3. Custom Osteotomy Guides

Further developments of 3D customizing of non-implantable devices are the patient specific cutting guides. They are custom-made masks created with the aim of guiding the femoral neck cut. The design and realization of a custom-made guide requires a very accurate preoperative study. The best plan for the osteotomy should be chosen. Landmarks on the 3D model of the femur should be carefully chosen in order to be easily identified on the real bone during surgery. Volume of the cutting guide should be chosen according to the type and dimension of surgical approach. The cutting guide is tailored to be perfectly suitable for the patient's anatomy. Therefore, guides are moulded by CAD software, looking for the best precision of the cutting planes, a good stability and the lowest possible encumbrance. Unfortunately, often obtaining a good version of the guide in terms of precision, stability and easiness of use is not easy and requires several attempts and tests. Nylon 680 or PA 2200 are the most frequently used materials because they are radiolucent, biocompatible and sterilizable and present excellent mechanical properties. Since the blade of the saw is not radiolucent, intraoperative fluoroscopic control is possible to check the proper position of the guide (Figure 5).

Figure 5. Intraoperative fluoroscopy showing a correct position of the guided neck osteotomy.

IMPLANTABLE 3D CUSTOMIZED COMPONENTS

Complex Primary Hip Replacement

Total hip arthroplasty is well defined in most cases and described principles should be followed to obtain the expected functional results and for long term implant survival [13]. Biomechanics of the hip must be respected: restoration of the centre of rotation, of the lever arm and correct positioning of implants are essential to limit impingement and components wear.

As said above, primary THA may also be complex: anatomical deformities may be an issue for the surgeon. Coxa vara, leg length discrepancy, acetabular dysplasia, Legg-Calve-Perthes disease, epiphyseolysis, heterotopic ossifications, avascular necrosis of femoral head, trauma in acetabular traumatic fractures are the most common ones. Bone dystrophies (Paget's disease, osteoporosis, osteopetrosis, radiated bone) may also complicate the surgical steps. 3D customized implants may be useful in those severe deformities.

In the last decade, introduction of modularity has been as an alternative to monoblock femoral stems. Large use of modular implants has been made in primary complex arthroplasty. As widely proved in literature and by experience, it shows remarkable advantages. The claimed advantage of this type of prosthesis is the possibility of choosing intraoperatively neck version and neck length independently of the stem size. With modular neck, restoration of hip biomechanics including femoral offset and soft tissue tensioning and abductor muscle imbalances, is easier, mostly in complex hip replacement [5-7]. However, an increasing number of recently published reports and studies describe failures of modular femoral neck prostheses. The addition of an interface is associated with complications such as corrosion or stem-neck disassociation [14-15].

Another option for complex hip arthroplasty is the implant of short stem. Short stems may be used in selected morphological anomalies of proximal femur in younger patient with a good bone quality. Unfortunately only a little rate of complex arthroplasty may be safely performed using short femoral stems, for example coxa vara and high dysplastic femoral neck anteversion are known contraindications [16, 17].

Several surgical techniques have been also proposed to improve implant positioning and stability in complex arthroplasty. Classic shelf augmentation, cotyloplasty, medial protrusion technique and a controlled fracture of the medial wall are the most known. Osteotomy of the iliac ala with distal sliding of the detached fragment, proximal positioning of the acetabular component, proximal femoral shortening osteotomy, sub-trochanteric shortening and/or derotation osteotomy have also been widely used [13, 19]. All of them are still considered as reliable in specific group of patient but 3D technology may decrease their popularity.

Femoral Customizing

Literature reports several studies about custom-made femoral implants for femoral deformities. Each patient with major deformity of proximal femur is a unique case. The complex femoral anatomy in combination with soft tissue and leg length discrepancy precludes the implantation of classical stem in several situations. Use of modular stem or cone type stems can solve most of the cases. When excessive rotational deformity, coxa vara and cortical thinning are present and no anatomical fitting could be achieved with standard stems, a custom femoral implant should be considered. A custom design may improve strain distribution and help to reconstruct hip biomechanics. Abnormal helitortion of proximal femur is treated creating an asymmetrical proximal part of the stem and neck geometry may be corrected in a triplanar way. The main purpose is to follow canal morphology by varying the implant surface in contact with the bone. This approach is named "fill and fit." It consists in the physiological distribution of stress to the femoral shaft. Stems are normally designed with circular cross section and stem tip has hemispheric shape in order to facilitate the

implantation to the femoral canal and avoiding localized stress shields. All reported custom-made femoral stems are made of titanium alloy. Bone integration is helped by surface settings: specific roughness and hydroxyapatite coatings. In the majority of custom-made femoral stem, the hydroxyapatite coating is applied to the proximal part of the implant although, some authors used a fully hydroxyapatite coated stem [20, 21, 24, 25].

Furthermore custom stems present all the advantages of monoblock design: no stress concentrations at the neck and stem junction and a low rate of aseptic loosening.

The main disadvantages of custom-made femoral stems are the long production time and the high cost. Production times can take up to three months. The work flow includes the selection of images from CT scans and the production of a prototype that has to be sent to the surgeon, who can approve or modify it. This process can be repeated several times before achieving a perfect stem. Costs increase two or three times if compared to the production of a standard stem.

In cases of severe dysplasia, custom-made stems may simplify surgical procedure, avoiding in several cases trochanteric osteotomy, which may increase complication rates. The femoral cut height and direction is either preoperatively decided by CAD measurements, or obtained by creating custom-made cutting guides. Preparation of femoral canal is done with one or two custom-made broches, usually 1 mm smaller than definitive stem. Broaches have the same shape as the custom stem. Femoral anteversion, varus/valgus correction, lateral offset are defined in preoperative planning. In those complex cases, custom-made implants may increase life expectancy of stem and reduce revision rate. Literature showed high rates of stem survival prosthesis (from 93% to 100% in a range from 6 to 14 years follow up). All studies demonstrated a significant improvement in postoperative clinical score compared to preoperative situation. No studies reported major complications after custom-made femoral stem implantation.

Considering the available huge variability of solution (i.e., modularity, short-neck stems) an expert surgeon does not need custom-made prostheses for the standard first total hip arthroplasty. On the other hand, in severe deformities, custom-made femoral stems are a valid choice. According to our point of view, custom-made stems should be used when an accurate preoperative planning shows the impossibility to get a correct anatomic reconstruction and a good fitting. In those cases, the custom implant form is chosen in order to get an excellent stability, to achieve a better distribution of loads and a better reconstruction of hip biomechanics.

Cup Customizing

In severe acetabular deformities, cup placement may be technically difficult. Standard anatomic landmarks may not be identified therefore choosing cup size, inclination, anteversion and coverage may be complex. Several technique have been proposed to solve this issue [26-29]. These techniques use standard acetabular cup or, in more complex cases, of revision cups. Indication for custom-made cup in primary THA is rare but it should be considered in extreme cases: major alterations of acetabular anatomy, very small or very large dimensions of the acetabular cavity.

Illustrative Cases

Case 1: Diagnostic and Simulation Model for Preoperative THA Planning Plus Custom Cutting Guide for Intraoperative Neck Osteotomy (Figures 6-8)

Diagnosis: bilateral congenital hip dislocation. Severe anatomic alteration of the acetabulum with osseous ankylosis of the hip (locked in extension and outward rotation of 40 degrees). No leg length discrepancy.

Surgical plan: THA

Critical aspects: femoral head deformity with significant apposition of osteophytes, mainly anterior. Proximity of the femoral artery to the anterior osteophytes. Hip ankylosis, impossibility of flexion and internal rotation to help the osteotomy of the femoral neck through posterior-lateral access. Subsequent need of anterior access according to Smith Petersen with on-site osteotomy of the femoral neck.

Figure 6. TC 3D reconstruction of affected hip (case 1).

Figure 7. Multicolor 3D model showing real distance between femoral artery and femoral head (case 1).

Figure 8. Post-operative AP x-ray (case 1).

Customizing process: segmentation with separation of acetabulum from femur. Isolation of vascular structures, images acquired with CT scan with vascular phase. Production of two diagnostic and simulation models, one of them with coxofemoral articulation, the other one with the left half pelvis (subtraction of femur and vessels). Design of the femoral cut mask, created for two osteotomies: proximal cut to remove the femoral head and achieve a better visibility on the operating field, distal cut along the correct osteotomy line required for the definitive implant. Diagnostic and simulation model made of polylactic acid for exclusive preoperative use. Cutting guide made of sterilizable Nylon Taulman 680, suitable for intraoperative use. Both components were printed with FDM technology.

Preoperative acquired information: the real distance from artery and femoral head, individuation of a cleavage plane between the two structures, individuation of the femoral artery path (an arched path with anterior convexity).

Custom guide preparation: the guide for osteotomy was created on the complete model to carry out two osteotomies: a cranial osteotomy for the removal of the femoral head and a caudal one for the final osteotomy. Cup positioning was simulated on the model after subtracting the femoral artery and the femur, after preparing the acetabulum with increasing diameter reamer. Cup size has been estimated 46-48 mm, the best cup position at 45 degrees of coverage and 15 degree of anteversion was found.

Surgical procedure: Direct anterior access according to Smith Petersen. Cleavage plan was identified between the articular capsule and the femoral artery, which has been isolated and protected. Osteotomy was performed on site with the custom guide. The guide was made with holes for three pins in order to ensure its anchoring to the femoral neck and its stability while carrying out the osteotomy. The first cranial cut was performed to remove the femoral head, then the final osteotomy was carried out. Finally, the cup positioning met the preoperative design simulated on the 3D model. The final cup had a diameter of 48 mm with version, covering and direction of screws corresponding to what planned on the simulation model.

Case 2: Diagnostic and Simulation Model for Preoperative THA Planning Plus Cutting Guide For Biplane Femoral Osteotomy (Figures 9-11)

Diagnosis: Left hip arthritis on the Paget's disease of ipsilateral femur.

Surgical plan: left THA with long stem implant after biplane femoral correction osteotomy.

Critical aspects: severe deformity of left femur. Varus of 15 degrees and procurvature 4 degrees. Poor bone quality.

Customizing process: 3D femoral model printed by FDM technology, made of polylactic acid. Cutting guide was made of sterilizable and biocompatible Nylon PA 2200. Guide was made with lots for 4 locking pins and design to achieve a correction of the femoral deformity.

Preoperative step: The correction osteotomy was planned at proximal medium third of the femoral diaphysis. The partial (4.5 degrees) and not ideal (15° degrees) correction of the varus was planned; while a complete correction of procurvature was studied (3.7 degrees). In order to get these two corrections on the two planes, the exact distance of the cutting mask positioning was calculated: the distal cut should be made at 14 cm from the greater trochanter tip and the top edge of the guide should be at 11.6 cm. The simulation of the operation was carried out according to the following sequential steps: identification of the correct cut height, guide positioning with 3-mm pins, execution of both osteotomies, guide removal, bone wedge removal, stem implantation.

Figure 9. 3D TC reconstruction showing the severe femoral deformity (case 2).

Figure 10. Preoperative planning of biplanar osteotomy using custom made cutting guide (case 2).

Figure 11. Post- operative AP x-ray (case 2).

Surgical technique: Extended posterior lateral access according to Kocher Langebeck in order to expose the femoral diaphysis. Usual acetabular cup implantation technique. Split of the medial vastus and partial disinsertion of the gluteus maximus muscle with exposure of the femur shaft. Custom-made cutting mask was placed as per preoperative plan. Execution of the wedge-shaped biplanar osteotomy. Reduction of the femoral diaphysis and implant of long revision stem.

Case 3: Diagnostic and Simulation Model for Preoperative THA Planning Plus Custom Cup (Figures 12-14)

Diagnosis: bilateral hip arthritis in dysplastic acetabuli.

Surgical plan: bilateral THA with custom made cup and standard stem

Critical aspects: acetabular dimension and shape, anterior and posterior acetabular wall dimensions

Figure 12. Preoperative slice of CT scan showing the acetabular deformity (case 3).

Figure 13. 3D virtual image of custom cup with 1) iliac wing and 2) representation of screws direction (case 3).

Figure 14. Rendering of proposed cup with screws (case 3).

Surgeon's requests for custom cup: cup compatible with a ceramic 28mm diameter liner (minimum cup diameter 38mm), holes for at least two screws, customized iliac support to improve implant stability ensuring the correct coverage (45°) and anteversion (15°) of the cup as shown in the preoperative 3D planning.

Chapter 152

3D CUSTOMIZING IN REVISION HIP REPLACEMENT

***A. Aprato*, A. D'Amelio, F. Marra, M. M. Favuto,
D. Mellano and A. Massè***

University of Turin, Turin, Italy

ABSTRACT

Revision surgery represents a challenging procedure, especially when it is not a first time revision. 3D technology helps in the comprehension of complex bone defects and drives the surgeon through the treatment planning and the procedure itself. Modern 3D printing may be used to create anatomical models and component trials for surgical preparation; the surgeon may try cup size, positions, screw directions and measurements and thickness of available bone for implants placement, drastically reducing surgery times.

Regarding the femoral side, in the last few years, custom-made implants have been proposed for patients undergoing revision hip surgery. However, nowadays, long-stemmed standard implants or modular distal stems are more cost-effective than custom devices in revision surgery. For this reason, their use is not frequent.

In cases of large acetabular bone loss, the goal is to provide a stable fixation of the cup, trying to fill the periacetabular bone defect and restoring correct centre of rotation of the hip. The custom 3D-printed acetabular implant has been introduced in the last 20 years as an exciting new option to address severe acetabular bone loss. These solutions are built custom-fitted to patient's anatomy, obtained from CT reconstruction, to allow a broad stress distribution and best possible fit between bone and implant surface, and to restore a good joint biomechanics.

Custom-made implant can be a reliable option either in Paprosky III A/B cases or in pelvic discontinuity. According to reported data in various arthroplasty registers, the demand for these implants will increase in the next years. Unfortunately up to date, there is still a lack of consistent published data, but preliminary results encourage this course.

INTRODUCTION

Revision hip surgery procedures are becoming increasingly frequent due to the larger number of primary hip replacement performed over the last 20-30 years, according to the data reported by various National registers [1, 2]. The incidence of Total Hip Arthroplasty (THA) is increasing, a doubling of revision procedures is expected by 2026 [3]; consequently the need for hip revision surgeries will increase. Revision surgery often represents a challenging procedure, mostly when it is not a first time revision. The most common causes are aseptic loosening (55.2%), dislocation (11.8%), septic loosening (7.5%) and periprosthetic fractures (6%) [3]. Each of these conditions may be associated with mild or advanced bone loss. The etiology of bone loss after THA is multifactorial. Stress shielding, massive osteolysis, extensive loosening and history of multiple surgeries consist the most common etiologies. The correct identification and classification of the bone loss is mandatory in order to provide a correct solution. 3D technology helps in the comprehension of complex bone defects and drives the surgeon through the treatment planning of the revision surgery. Complex problems affect the acetabular side more often than the femoral one. Several implant solutions were proposed over the years to revise an acetabular cup in a bone loss condition. Custom-made acetabular components, obtained with a 3D technology, may be useful in cases where previous implants have failed resulting in a huge impairment of the periacetabular bone stock. There is still a lack of consistent published data, but preliminary results encourage this course.

The amount of bone loss can be both femoral and acetabular. To describe the amount of femoral bone deficiency, the classifications proposed by AAOS Committee on the Hip [4] and Della Valle Paprosky [5] are commonly used. Usually accurate measuring the osteolysis has been notoriously difficult, particularly in the acetabular area. The patient's diagnostic workup starts with standard X-rays. Plain radiographs are the most common way to assess the osteolysis, due to low cost and easier use. AP pelvis, full-length femur radiographs, and oblique acetabular end views of the involved hip are the most common radiographic projections used during the follow-up of patients underwent Total Hip Arthroplasty. The comparison with previous radiographs is usually the first element for osteolysis measure. A single radiograph has an overall sensitivity for the detection of osteolysis of 40% (which increases to 70% when all four radiographic views of one lesion are analyzed together), and a specificity of 70-90% [6]. In contrast to femoral osteolysis, periacetabular pelvic osteolysis is not well defined on a single AP radiograph of the pelvis. Lateral view of the hip frequently does not give specific information about the pelvis. Multiple radiographic views can be used to evaluate acetabular bone loss preoperatively in planning for revision THA [7]: iliac oblique view and obturator oblique view can be helpful specially to identify posterior column lesions, but must be inspected carefully to recognize stress shielding from an osteolytic lesion; they can be used when dubious osteolytic lesion is evidenced on standard views. Although radiographs can be useful to screen for clinically relevant pelvic osteolysis, CT images are necessary to accurately measure the volumes of the lesions. It is generally accepted that plain radiographs are not sufficiently sensitive for periprosthetic osteolysis evaluation because the measurement of lesion size and their location is often incorrect, and thus, the amount of bone loss can be underestimated. CT-scan is more accurate to define the size, precise location, extent of bone resorption and has more sensitivity (90% of lesions are detected). Size and location of a periprosthetic defect are not the only dimensions of interest in the preoperative

analysis of a failed acetabular implant: up to date surgeons would like to know the quantity and quality of the bone, the further bone loss expected from the implant removal, the quantity of auto or allograft needed, the dimension of the implant to fill the defect. In order to study periacetabular osteolysis, specialized softwares for CT scan image analysis have been developed.

3D PRINTING

Imaging 3D and CT scan are not the only way to perform an accurate preoperative planning. 3D printing is a manufacturing process: materials (such plastic, metal, ceramics, powders, liquids or even living cells) are deposited in layers to create a 3D object from digital data.

The process begins with the acquisition of images (usually images in Digital Imaging and Communications in Medicine [DICOM] format); then the acquired images are uploaded for 3D reconstruction and converted into a 3D printer compatible format. The 3D printer first follows the instructions in the Custom Assisted Design (CAD) file to build the foundation for the object, moving the printhead along the x–y plane. The printer then continues to follow the instructions, moving the printhead along the z-axis to build the object vertically layer by layer [8]. Creating patients-specific models has many practical applications. Modern 3D printing may be used to create anatomical models for surgical preparation, for example the surgeon may try cup size, positions, screw directions and measurements and thickness of available bone for implants placement, drastically reducing surgery times. In the assessment of pelvic discontinuity, a 3D model can give to the surgeon a real prospective of how much bone and which quality it has in ensuring a pelvic ring continuity. Models printed with thermoplastics then can also be sterilized and used as intraoperative templates.

COMPLEX REVISION HIP ARTHROPLASTY

Revision hip arthroplasty, especially when multiple revision, is one of the most complex topic in orthopaedic surgery. Each case represents for the surgeon a specific challenge because of the patient's unique anatomy both on the acetabular and femoral side. Usually revision, presenting bone defects equal or worse than Paprosky III/AAOS III on the femur and Paprosky III on the acetabulum, are considered as complex.

Aims of femoral revision are stable and durable fixation of the implant and restoration of the bone stock. Obtaining the stable fixation of the stem could be challenging because of the severe bone loss. In case of proximal bone defects usually taper conical modular stems designed to get a diaphyseal fixation are used. They allow also to restore lower limb length and femoral neck version. In metaphyseal or diaphyseal bone defects instead, strategies include biological or non-biological solutions. Impaction grafting, structural grafts and so-called composite implants are biological solutions to fill the bone loss. Non-biological solutions include metal meshes, megaprotheses or even total femur replacements [9, 10].

In cases with large acetabular bone loss the aim is to provide a stable fixation of the prosthetic component, trying to fill the periacetabular bone defect and restoring correct centre

of rotation of the hip. Those bone losses may be managed using cemented or uncemented cup implants, in combination with impaction grafting, metal meshes or reconstruction cages, or structural bone grafts [11, 12, 13, 14].

Classification of the bone defects may not be accurate compared to the intraoperative findings for the presence of metal artefacts; those can also impair the right understanding of the relationships between acetabular region and intrapelvic structures. Removal of an excessively medialized prosthetic cup may be dangerous because of proximity of pelvic vessels, ureter and bladder, usually with lot of scar tissues between those structures and the prosthetic component in more complex cases [11]. This represents a challenge either in the phase of preoperative, either intraoperatively. For the functional outcomes, it is very important to restore the correct centre of rotation of the hip and this often should to be obtained with a lateralization and distalization of the acetabular cup [15]. Such needing can be very difficult to satisfy in cases of large bone defect where acetabular solutions at the same time have to play the socket role in the right joint position, fill the gap around it in a mechanical valid manner and reach up in the ilium a good zone with an enough contact area to obtain a stable fixation between the prosthetic component and the cancellous bone.

Surgical approach can be also very demanding. The posterolateral approach is the most widely used and very familiar to hip surgeons. It can be used for complex revisions, with the acetabulum exposed by pulling the femur anteriorly [11, 16]. Release of gluteus maximum, anterior capsule and reflected head of the rectus femoris is often mandatory to get an adequate mobilization of the proximal femur to address the acetabulum. Also the direct anterior approach, since its increased popularity among surgeons, has been described as a valid approach to manage cases of extensive periacetabular bone loss. With this approach, however affected by a long learning curve, the exposure of the entire ilium cranial of the acetabulum can be achieved, and also the pubic bone as well as intrapelvic structures adjacent to the acetabulum can be exposed [17]. Authors then described an extension of the direct anterior approach for accessing the femoral diaphysis that allows for easy access to the lateral aspect of the vastus lateralis and the femoral diaphysis. Using this technique, depending from authors' opinion it should also be possible to access the femur and perform all necessary reconstructive procedures [18]. Some authors use the anterolateral and direct lateral approaches reporting postoperative stability avoiding damages to posterior neurovascular structures. However, the potential postoperative morbidity associated with violation of the abductor complex cannot be ignored [16]. Another approach described for complex acetabular revision cases is the extended iliofemoral approach that provides a better exposure of the anterior column, at the price of a more invasive procedure in terms of surgical time, blood loss and tissue damage [19]. In case of severe intra-pelvic migration of acetabular component then, with the help of general or vascular surgeons, retroperitoneal approach or trans-abdominal approach should be considered to prevent several serious intra-pelvic complications, including vascular injuries, which have been reported when acetabular component removal was attempted through the defect in the inner wall of pelvis [20]. Although single-component revision may be planned, the surgical approach should not limit the ability to perform revision of both the femur and the acetabulum if necessary.

CONVENTIONAL IMPLANTS AND SOLUTIONS

Regarding the femur, as mentioned before, some different solutions including biological or non-biological options have been described to revise a prosthetic component in case of a significant bone loss condition. Among non-biological solutions uncemented femoral fixation has become the preferred method to achieve long-term stability [10]. The most commonly used components in complex revision procedures include extensively porous-coated stems, modular stems with cone-conical constructs, and in selected cases, megaprotheses. Extensively porous-coated stems are the best option for most femoral revisions with a good survivorship reported, even if stress shielding phenomena with thigh pain can be associated. Hamilton examined 905 femoral revisions performed with this type of stems from 1980 to 2006. The cohort showed a re-revision rate of 2.2%, with a 1.3% incidence of aseptic loosening [21]. Weeden and Paprosky evaluated 170 revisions with fully porous-coated stems, and the overall rate of failure in the entire cohort was 4.1%. Follow-up imaging showed evidence of ingrowth in 82% of patients, but 4% of patients presented with a radiographically unstable stem [22]. The highest rates of failure in these series were seen in patients who had worse bone stock with a Paprosky type IIIB condition. Sporer and Paprosky reported a poor survivorship in femurs with canal width greater than 19 mm or large defects in the femoral isthmus. In these cases, the authors recommended impaction grafting or use of a modular tapered stem [23]. Tapered, fluted, porous-coated stems, as the Wagner stem, were developed to address stress shielding associated with extensively porous-coated implants, with a good rate of success. However monoblock tapered implants are commonly affected by risk of instability, for abductor weakness, and leg length discrepancy because of the inherent difficulty in determining the level of implant seating that would provide axial stability. The more recent introduction of modularity allowed surgeons to overcome some difficulties of monoblock stems in ensuring good functional outcome. However, the addition of modularity brings the risks of implant breakage at the modular junction and taper corrosion [24]. Richards examined a series of 115 revision procedures, of which 65% were Paprosky type IIIB or type IV, and reported 87% survivorship at 3-year follow-up [25]. A salvage option could be proximal femoral replacement, despite disadvantages such as early loosening, instability, limb length discrepancy and associated sciatic nerve palsy, and impairment of remaining proximal femoral bone stock. Such implants provide immediate stability and predictable results. In a study reporting results of proximal femoral arthroplasty for nonneoplastic conditions at about 12 years of follow-up, the overall survivorship was 64%, with however almost half of the patients had substantial ambulatory dysfunction (severe limp or inability to walk) [26]. In case of massive bone loss proximal femur replacement can be used and when the distal anchorage cannot be achieved at all, the use of a total femur prosthesis represents a viable alternative [27]. Cemented stem alone have shown very poor results in management of femoral revision in severe bone defect conditions. Coming to the role of biological option, some authors reported encouraging experience in young and active patients affected by Paprosky IIIB or IV bone loss, using cemented stem managed with the modern third-generation cementing techniques in combination with impaction grafting [10]. Risks associated with this technique are intraoperative and early postoperative periprosthetic fracture, stem subsidence, and construct failure. In a Swedish cohort of 1305 patients has been reported a 94% survival at 15 years, with only 0.9% of signs of aseptic loosening [28].

More recent studies showed a 96% stem survival rate at 17-year follow-up, with average reported subsidence of 3 mm [29]. Particulate and cortical structural allograft may be necessary in the setting of Paprosky type IV when proximal femoral replacement prosthesis is undesirable. Proximal femur is removed and the long-stem revision prosthesis is then press-fit or cemented into the proximal femoral allograft, and this allograft prosthetic composite is mated with the distal host femur, with the distal prosthetic portion press-fit or cemented into the canal. Main advantage is the chance to restore bone stock and facilitate reattachment of host soft tissue, even if functional recovery can be unpredictable, and dislocation may necessitate acetabular revision. Recent studies with allograft prosthetic composite in revision surgery have shown a success rates ranged from 66% to 95% [30]. However, the surgical technique is technically demanding, and could be not so easy to obtain an ideal amount of allograft.

Regarding acetabulum combined cavitory and segmental defects, particularly those without superior acetabular coverage, preclude the use of a conventional cementless cup [11]. Such defects have been addressed with the use of allograft in combination with rings and cages, highly porous metal cups and augments with or without a cage [31, 32]. Some authors described also how to convert uncontained defects into contained defects using flexible reconstruction meshes, providing a stable cavity for impaction bone grafting reconstruction and cemented cup fixation [11]. A cementless component alone may not be sufficient in Paprosky type III defects. In type III A defects, if the contact of the component with the remaining host bone is more than 40-60% it is reasonable to expect a durable bone in-growth. Impaction bone grafting allows bone restoration, with different preparations of allograft. Fresh-frozen bone or freeze-dried bone can be used, with the first option characterized by better results but a theoretical risk of transmission of contagious diseases. Irradiation in freeze-dried bone reduces graft immunogenicity and enhances graft incorporation. However freeze-drying can reduce the mechanical properties of the graft and diminish its capacity for structural support [33]. Interesting results came out from the use of demineralised bone matrix and bone morphogenic proteins in impaction bone grafting [34]. In cases with a defect of the superior dome and proximal migration of the acetabular component (Paprosky type III A) use of a hemispherical porous coated component alone cannot ensure a stable fixation. Better results are reached using a structural allograft in association. Paprosky published satisfactory results of severe acetabular defect treated with cemented component and bulk allografts [35]. It was described a technique with the use of distal femoral or proximal tibial allograft and cementless cups to reconstruct the acetabulum, because orientation of the trabecular bone in these allografts provides better mechanical support for the implant compared to a femoral head allograft. Given radiographic signs of loosening as the endpoint, construct survival at 10 years of follow up was 74% [36]. However failure rate is high when structural grafts support areas larger than 50% of the acetabular component. Reinforcement rings are designed to manage minor segmental defects with more than 50% of native bone intact, while in type III defects with moderate superior hip centre displacement, disruption of the teardrop, and Kohler's line was traditionally used the Burch-Schneider cage [12]. In general, structural grafts replacing more than 50% of the acetabulum require protection by a cage. These components allow for restoration of hip centre, and providing uniform load to the allograft, either the morselized or structural grafts, stimulate bone remodelling and incorporation into host bone [31]. However there is a higher risk of neurovascular injury since large exposure of the ileum and ischium is needed to anchor the cage [12]. Recently published data showed

survivorship rates of 87.5% (56 hips) after 11.7 years and 72.2% (18 hips) after 13.5 years [37]. In cases of large acetabular bone defects, the antiprotrusio cage should have a larger contact area with the remaining host bone and rigid primary fixation with screws. Mechanically, reinforcement rings or antiprotrusio cages should be considered as an internal fixation plate for the acetabulum. The placement of the screws is important to prevent micro-motion of the cage and subsequent defragmentation or resorption of the graft [11]. This is important because in case of lack of biologic fixation the Burch-Schneider cage is at risk of breakage or loosening. However, if the graft had enough time to remodel itself before the cage fracture, a subsequent standard cementless acetabular revision could be possible [38], but with another not easy surgical procedure due. Indications for bulk allograft and for morselized allograft with a reconstruction cage in major acetabular defects are still unclear [11]. More recently trabecular metals such tantalum, have been introduced as a powerful tool for reconstruction of the failed acetabular component [39]. The increased porosity, high coefficient of friction, and favourable elastic modulus of porous tantalum compared with traditional titanium mesh or cobalt chromium acetabular components allow for greater bone in-growth potential, implant stability, and host bone preservation. To supplement acetabular fixation when there is segmental bone loss, acetabular augments can be used to fill specific defects. These augments can theoretically replace the need for structural allograft and can be used alone or in combination with other augments. Specific reamers allow to prepare the acetabular defect where augments will be placed. The augments are then impacted into the defect and fixed with screws. However these augments are made with standard shapes and dimensions and so they do not fit every time so good to the host bone. Once the augments are in place, hemispherical cup can be press fitted into the acetabulum with cement placed at the augment-cup interface. So far mid-term follow up results are satisfying with reported success rate around 98% [40, 41]. An alternative option to correct large acetabular defects is the cup-cage construct; a second generation porous cup fixed in the pelvis in combination with an acetabular cage can be placed on top of the cup and secured with screws into the ilium and ischium. In this way the cage removes loading forces on the cup and allows time to optimize ingrowth of new bone into the cup [42]. Cup-cage construct can be used to manage not only Paprosky type III A and III B bone loss but also pelvic discontinuity, with some good results reported [43, 44]. Radiographically stable fixation at 2-year follow-up has been reported with the use of tantalum augment alone, combined with impaction grafting, and with a cage-cup construct [45, 46, 47]. All these solutions showed good results in cases of complex acetabular bone loss, but they could require several surgical steps and in some cases they still have a high failure rate. For this reason industry is ever working on innovation and custom-made components obtained with a 3D technology are an interesting alternative for the surgeon.

IMPLANTS AND SOLUTIONS WITH 3D TECHNOLOGY

The custom 3D-printed acetabular implant has introduced in the last 20 years as an exciting new option to address severe acetabular bone loss. This kind of solution is indicated in complex cases with a multiple revision history associated with poor bone stock. It can be a viable option either in Paprosky III A/B cases or in pelvic discontinuity [48, 49, 50], and according to reported data in various arthroplasty registers, with ageing populations and

trends for total hip replacements in younger patients it is likely that the demand for these implants will increase [51]. The goal of this kind of implants is to allow a restoration of the acetabular anatomy, filling the periacetabular bone defects and restoring hip biomechanics, with a stable fixation of the implant to the host bone. Implant stability is ensured by screws introduced through prepared holes in three flanges spreading from the component and laying on ilium, ischium and pubis. Presence of these flanges, in the beginnings, gave the name to this kind of solutions, known as triflange cup. The implant can be tailored with different zones depending on specific mechanical and biological problem to address. Porous surfaces are used to promote bone on-growth while smooth surfaces can diminish potential irritation of soft-tissues. Depending on the CT scan data, locking screw trajectory and length can be planned to maximize fixation, to obtain the most efficient purchase in host bone and to minimize vascular risk. Previous implants removal has to be performed being careful not to further compromise the residual bone. Then periacetabular bone has to be prepared to receive the customized implant as planned. The aim is to achieve a good amount of contact surface between component and vital bone, without removing too much tissue. The precision-fit of the implant to the remaining patient's bone stock minimizes the need for more bone resection to fit a standard acetabular revision component. At this point 3D printed trial models of the involved hemipelvis and of the customized implant, suitably sterilized so that can be handled by members of the surgical team, provide visual and tactile reproduction of the deficient pelvic bony anatomy and of the mutual relationship with the component. This, besides the mentioned help in the preoperative planning, enables and improves understanding of the anatomy during surgery, facilitating intraoperative decisions. Depending on the patient's specific anatomy and the resulting chosen solution, the main cavity is reamed until the diameter planned, and also the nearby defects can be minimally reamed with smaller dedicated instrumentation to even out any roughness and to allow better fitting of any eventual bumps of the custom implant. Component is fixed to the hemipelvis by the porous metal back surface through a press fit concept, and usually by some locking screws going into ilium, ischium and pubis. Screws can be inserted from holes eventually present inside the cup, or from holes on flanges of the component. Then a liner is introduced inside the metal back either with or without cementation, depending on the implant concept design. Ceramic or new generation polyethylene liners are used.

Also regarding the femoral side, in the last few years, custom-made implants have been proposed for patients undergoing revision hip surgery, with the goals of promoting axial stability and preserving proximal bone stock. Different types of uncemented femoral stems have been designed. These stems were made individually using computer design and manufacturing technology. Custom-made femoral stems have been developed usually for younger patients with the objective to attain contact all around medial and lateral stem in the metaphysis and diaphysis of the femur. These solutions are built custom-fitted to patient's anatomy, obtained from CT reconstruction of the femur, to allow a broad stress distribution and best possible fit between bone and stem surface. However nowadays, long-stemmed standard implants or modular distal stems are more cost-effective than custom devices in revision surgery. For this reason, their use is not frequently seen.

ILLUSTRATIVE CASES

In this paragraph two illustrative cases of acetabular custom implant performed in our department are presented. One case was a pelvic discontinuity and one case was a Paprosky IIIB acetabular defect. The first case was an 81 years old lady affected by osteoarthritis of the left hip and who underwent a primary total hip arthroplasty when she was 70 y.o. Then a first revision of the stem was performed two years later to address the thigh pain. After three years, an aseptic loosening of the acetabular cup was noted; therefore the patient underwent acetabular revision. A new mobilization of the cup occurred then five years later and a new acetabular revision was performed with a standard revision component (Delta TT Revision, Lima Corporate). After few months three subsequent episodes of dislocation occurred, so the patient underwent a changing of the acetabular liner and a dual mobility solution was implanted. All these procedures were performed through a posterolateral approach. The patient had no more dislocation episodes, but started to feel a groin pain, worsening over the following months and affecting before daily activities and then even walking and standing. The patient was referred to our department where, after a new X-ray check (Figure 1) and a CT scan (Figure 2) of the pelvis, a new mobilization of the cup associated to a pelvic discontinuity was diagnosed. No clinical and laboratory signs of infection were registered over the clinical steps. Patient was in good general health conditions. In consideration of patient's age and of previous surgeries the aim was to find the best option to definitively address both the pelvic discontinuity and the cup mobilization. A custom-made acetabular component was proposed. Contrast CT scan images and relevant clinical data were sent to the engineering unit of the medical device company (Lima Corporate). Engineers focused on some topics of the preoperative situation as the periacetabular bone loss in a scenario of a poor bone quality, the need to restore the correct centre of rotation and the need to fill the large cavity in correspondence of the Anterior Inferior Iliac Spine. A 61 mm of diameter Titanium alloy (Ti6Al4V) cup was designed with an augmentation as a support for the iliac wing. Trabecular Titanium was scheduled on surfaces where a contact with the host bone was planned and on the iliac support. Cup was designed to accept one of the Delta liner components (Lima Corporate), with dual mobility and elevated rim option. Iliac posterior (Figure 3), ischial and pubic flanges were designed to obtain primary stabilization through four 6,5 mm locking screws. Other two 6,5 locking screws were planned from inside the cup to reach a good quality bone in the iliac wing avoiding zones impaired by any previous screws. These two screws were custom-made to obtain the desired length. Implantation of the components was planned through standard instruments, except for a customized 37 mm of diameter reamer designed to prepare the cavity in correspondence of the Anterior Inferior Iliac Spine. A 3D trial of the hemipelvis without previous implants and one of the designed custom-made component were printed and provided to be sterilized. They have been used in theatre helping the surgeon in the surgical steps (Figure 4). Planned solution was analysed and approved by our hip team leader. Surgery was performed on June 2016. During component removal, as expected from imaging evaluation, a bleeding from a collateral ramus of the superior gluteal artery was managed by haemostatic matrix with thrombin. Intraoperative samples for bacteriological examination were collected, with negative postoperative result. In contrast with preoperative plan, the surgeon did not insert the pubic screw: this because in that zone the perfect fitting of the component was not obtained,

probably due a suboptimal preparation of the cicatrized soft tissues around. Therefore the hole designed would keep the screws in a different direction, useless to gain more stability than the adequate already obtained. An elevated rim new generation polyethylene liner was implanted (Figure 5). Rehabilitation started on the 2nd post-operative day with allowed partial weight bearing for the first 6 weeks.

Figure 6. Pre-op x-ray of an aseptic acetabular loosening on a solved pelvic discontinuity scenario (case 2).

Figure 7. CT scan of the pelvis (case 2).

The second case is a 61 years old lady with an aseptic mobilization of the cup with a Paprosky IIIB acetabular defect in a solved scenario of pelvic discontinuity. The patient underwent a first bilateral total hip replacement for developmental dysplasia of the hip in 1996 at the age of 42 years old. Subsequently a first revision for aseptic loosening of the acetabular cup on the right side was performed in 2002, using a Burch-Schneider ring. After the ring failure occurred nine years later, the patient underwent a third revision of the acetabular side in association with a reconstruction of the posterior column through a femoral head allograft fixed with a reconstruction plate. After one year the patient suffered of a new mobilization of the cup in a pelvic discontinuity scenario, so a forth revision was performed. A rib graft from the patient's chest was splitted and used as autograft to reconstruct the anterior and posterior acetabular columns [52]. Then a stemmed cup was implanted as the fifth acetabular revision. However a new mobilization with a breakage of the stemmed cup occurred after one year. As seen in the pre-operative radiological studies also during surgery was detected the healing of the pelvic discontinuity. So the Paprosky III B defect was then for the sixth time addressed with porous metal revision cup and augment. The surgeon was not able to remove all the metal work resulting from the previous solutions failure. At the beginning of 2016 the patient suffered a new mobilization of the acetabular components (Figure 6). Infection was ever excluded over every clinical step. Despite the patient's age, in consideration of the several previous fails we decided to submit the case for a custom-made acetabular solution. Again the patient underwent a CT scan, and the images and relevant historical data were sent to the engineering unit of the medical device company (Lima Corporate). Engineers focused on problems in hardware removal (i.e., the broken stem had to be removed, while was planned to leave in place the reconstruction plate on the anterior column), bone defects filling and component fixation. The company reported that was technically demanding in this case to minimize the metallic artefacts in the CT scan images due to the presence of the residual hardware (Figure 7). During the component design, attention was paid on the screw holes to possibly obtain a polyaxial screws placement in order to prevent, for example, difficulties encountered with the pubic screw. Here the 3D trials gave an important help in the comprehension of this topic (Figure 8). A 63 mm of diameter

Titanium alloy (Ti6Al4V) bilobate cup was designed with a conical peg of 28 mm of length and 19 mm large at the basis to fill the iliac defect after the broken stem removal (Figure 9). A little ischial flange was designed with holes for two 6,5 locking screws. Iliac stabilization was planned through the peg and a 6,5 locking screw crossing two holes in both the lobes of the cup with 10 degrees of polyaxial freedom. Pubic stabilization was again planned with the possibility to insert a 6,5 locking screw from inside the inferior cup. Trabecular Titanium was scheduled on surfaces where a contact with the host bone was planned and on the iliac support: small meshed trabecular titanium was planned on iliac peg and on inferior acetabular cup, while large meshed was planned on superior integrated augment in order to lighten the component (Figure 10). Cup was designed again to accept one of the Delta liner components (Lima Corporate). No customized instruments were planned from the company to implant the components. Again 3D trials of the acetabular component and of the hemipelvis were provided from the company and sterilized to be used during surgery (Figure 11). Planned solution was analysed and approved by our hip team leader. Surgery was performed on October 2016. Intraoperative samples for bacteriological examination were collected, again with negative results. Previous broken stem removal was successfully performed with a special extractors set (Shukla Medical). Screws were removed too, while other minor hardware components instead were left in place in order to avoid any unnecessary bone removal. Compared to what was planned, the surgeon did not insert the optional pubic screw that could interfere with these residual minor hardware components. Acetabular cavity and superior bone defects were both reamed with a standard 62 mm diameter reamer, while the defect generated from the broken stem removal was reamed with a conical ream. A standard new generation polyethylene liner was implanted (Figure 12). Rehabilitation started on the 2nd post-operative day with allowed touch weight bearing for the first 8 weeks.

CONCLUSION

Continuous technological innovation is a great help for hip revision surgery. In complex cases, 3D technology allows to better understand problems of the original situation and to plan the most appropriate solutions in terms of surgical technique and components. The acetabular custom-made component seems to allow a good restoration of the articular

biomechanics, with a single component well fixed to the host bone. This may exclude some possible issues registered with modular constructs. Some improvements are needed to increase the correspondence between the planning and the surgical action. Up to now obtaining the best fit of the custom component with the patient's anatomy is not easy. These solutions are recent and the number of cases of each centre is still small, but first outcomes are encouraging, and further data are required to support their use.

Orthopaedic and Trauma Center, Turin, Italy

ABSTRACT

Musculoskeletal tumors are a very rare entity and malignant bone tumors such as osteosarcoma are even more rare in the pelvic region. The resection and reconstruction of these tumors lead to some difficulties due to the high risk of incomplete resection and high residual functional impairment. Recently developed 3D technologies give some relevant advantages in the complex tridimensional geometry of the pelvis: a more accurate preoperative evaluation of the margins of resection and of the relationship between noble structures and the tumor, and a new instrument to explain the surgical procedure to the patient.

Computer-assisted orthopaedic surgery (CAOS) is a discipline where computer technology is employed to improve the outcome of orthopaedic surgery. 3D technologies have been also adopted in musculoskeletal oncology and a new discipline, called Computer Assisted Tumor Surgery (CATS), has been introduced. 3D technologies and CATS permit to design and realize patient specific cutting guides, to simulate surgical navigation over a previous planning and intraoperatively navigate the resection.

3D printing of custom made implants for the reconstruction is the more advanced feature of these technologies. Theoretically any kind of anatomical site could be reconstructed after tumor resection with 3D custom implants, but the pelvis is the elective one because of its anatomic peculiarity, the duration of surgery, and the difficulty to obtain stable and long-lasting reconstructions.

3D customizing is an innovative and expanding field in orthopaedic oncology and especially in pelvic lesions. Preoperative study, resection, intraoperative navigation and custom made implants are nowadays viable options for treating pelvic tumors.

1. INTRODUCTION

Musculoskeletal tumors are a very rare entity, and benign or locally aggressive tumors are greatly more frequent than malignant tumors, for about two orders of greatness (and they almost double them). It has been calculated that the annual burden of soft tissue and skeletal malignant neoplasms (so-called sarcomas) is around 30 cases per million worldwide, resulting in nearly 3000 per million cases of benign lesions [1, 2]. Primary malignant bone tumors such as osteosarcoma are very rare in the pelvic region because they are much more frequent in the limbs, especially around the knee. On the other side chondrosarcomas and Ewing's sarcomas quite commonly affect the pelvis. The surgical resection is usually one of the key-point of the treatment in primary bone tumors, especially if we consider that chondrosarcoma does not respond to chemotherapy and radiotherapy. Pelvic lesions are complex also for their huge dimensions: in the pelvic cavity a tumor can grow for a long time and achieve a large diameter usually without pain or relevant symptoms. Alternatively around the hip joint (acetabulum and/or proximal femur) a lytic bone lesion usually become symptomatic very soon with pain during walking or weight-bearing, if not with a pathologic fracture.

Soft tissue sarcomas are more common than bone sarcomas and, when in the pelvic area, they usually invade the bone and require a bone resection to obtain clear margins. Therefore, in a simplified way from a surgical point of view, they could be considered as a bone sarcoma with soft tissues invasion.

On the other side, the pelvic ring is greatly affected by metastases. Following US and Canadian surveys metastatic bone disease involves along their life 50% of all patients with a primitive cancer and 30% of patients with a new diagnosis of carcinoma. Metastases involve in order spine, pelvis, and long bones [3–5].

This point radically modifies the surgical indications, with the predominance of non-surgical or minimally invasive surgical treatments, as described by recently published Italian Guidelines for metastatic disease of the pelvis [6]. Nevertheless, an early cancer diagnosis and new chemotherapy protocols determine an improvement in overall long-term survival sometimes obtaining the chronicization of the disease with a continue request of long-lasting and complex surgical interventions, mostly in the pelvic area.

The main problems for the surgeon facing a pelvic tumor are: the complex three-dimensional (3D) geometry and the proximity (or sometimes the invasion) of important organs (bladder, rectum, prostate, etc.) and neurovascular structures (iliac or femoral vessels, femoral or sciatic nerves). This complex and restricted working space can explain the high complication rate usually observed in pelvic bone tumor surgery. Potential complications in pelvic oncologic surgery are: massive bleeding, infection, local recurrence, vascular or neural damage, visceral organs damage, deep vein thrombosis, failure of the reconstruction, wound dehiscence often requiring flaps or advanced medications. These complications can deal to an amputation (usually hip disarticulation or hindquarter amputation) or even to the exitus. A particular focus is on the local recurrence rate ranging from 28 to 35%. An accurate resection with wide margins is required since it is highly associated with a low local recurrence rate [7].

Clear and adequate margins affect positively the outcome of the treatment of sarcomas. The concept of margins in orthopaedic oncology was introduced by Enneking [8].

Enneking classified the margins into 4 categories: intralesional, marginal, wide and radical. To obtain an adequate surgical margin is the principal goal of oncologic surgery. Pelvic surgery magnifies the problem: it is impossible to obtain radical margins due to the anatomic conformation (with the exception, of course, of a hindquarter amputation in selected cases). Enneking also divided the pelvis in four main surgical areas zones to classify the tumors in the pelvis: zone 1, the iliac wing; zone 2, the periacetabular area; zone 3, the pubic branches; zone 4, the sacrum. The tumor can involve one or more areas.

The reconstruction becomes more complex when the zone 2 is involved by the neoplasm and it should be partially or completely resected.

In this complex field, 3D techniques seem to be very attractive in studying, planning, explaining, and finally reconstructing complex cases.

The possibility of digitally recreating the 3D geometry of the tumor gives some relevant advantages:

- An easier case study for the surgeon with an accurate preoperative evaluation of the margins of resection and the relationship between potentially involved noble structures and the tumor
- An instrument to explain the surgical procedure to the patient
- An instrument to design and realize patient specific cutting guides
- The simulation of a surgical navigation over a previous planning
- The project of custom made implants for the reconstruction.

2. DIAGNOSIS

The diagnosis of a primitive or metastatic tumor of the pelvic ring or around the hip joint could be very demanding. Symptoms are seldom clear, with masses that could easily reach big dimensions. Sometimes the clinical onset is dramatic, due to periacetabular fractures or viscera compression.

Traditional X-Ray Imaging represents the first diagnostic approach but a further study with second level diagnostic exams such as Computed Tomography (CT) scans and Magnetic Resonance Imaging (MRI) is mandatory. Both CT and MRI are commonly used with contrast medium, to enhance vascularization and relationship with the major vessels of the pelvis. A biopsy is nearly always required, especially in case of suspected primitive malignant or benign aggressive lesion. In the pelvis the usual approach is a core needle CT guided biopsy following the general rules for biopsy according to the future definitive surgical access. The biopsy could be avoided only in case of a clear history of metastatic disease [6] or if the Imaging is absolutely indicative for a benign calm lesion.

When the histologic diagnosis is obtained, the orthopaedic oncology surgeon can face mainly 4 different clinical situations potentially dealing with 3D technologies:

- 1) *Benign lesions requiring an intralesional or marginal treatment.* These lesions are benign or aggressive-benign tumors (e.g., simple bone cysts, aneurismal bone cysts

or ABC, giant cell tumors of the bone or GCT, osteochondromas). The treatment could range from the marginal excision of the lesion to the intralesional removal of the pathologic intraosseous lesion (usually curetting) and the following filling of the residual cavity with bone grafts or bone cement. Some recent studies modified the surgical strategies with an increasing indication to minimally invasive or not surgical treatments. Curettage [9] has been described for the diagnosis and the simultaneous treatment of benign cystic lesions. ABCs were traditionally curetted out and then filled in with bone grafts; recently multiple exclusive embolizations [10] or the injection of demineralized bone matrix [11] or mesenchymal cells have been used with promising results. Systemic administration of Denosumab was recently introduced for the treatment of GCTs [12] but the protocols are still unclear whether it should be considered a neoadjuvant or an exclusive pharmacological treatment and in the first case whether the surgical treatment should be an extended curettage or a resection. In these lesions 3D technologies are useful in the pre-operative study and surgical planning combining CT and MRI, but rarely 3D printed implants have to be considered.

- 2) *Malignant primary bone tumors responsive to neoadjuvant treatments* (e.g., osteosarcoma, Ewing's sarcoma). Once obtained a diagnosis, a general staging with chest and abdomen CT scans is mandatory, because unfortunately lung and liver metastases are quite frequent even at the diagnosis. If the lesion needs preoperative chemotherapy and/or radiotherapy, a pre-treatment CT and MRI scan ideally have to be performed. A CT or MRI scan is usually performed during therapy cycles and a full general and local restaging is repeated at the end of the therapy protocol, in order to monitor tumor evolution. In some cases (e.g., responsive Ewing's sarcoma) the tumor could disappear and the oncologic treatments could be the only definitive therapeutic approach. When a surgical treatment is indicated a 3D planning and evaluation of the bone resection is advisable. An inadequate bone resection leads to positive margins or a high recurrence rate. On the other side an excessive resection can be impossible to reconstruct with a poor functional outcome. The reconstruction could be obtained with soft tissue or combined procedures (hip transposition or flailing hip), with allografts, or with available off-the-shelves prostheses (stemmed cups, ice-cream cones, saddle prostheses). In the case of a reconstruction with custom made implants, the decision should be made in advance (before the last or the second last chemotherapy cycle) allowing the time to produce the implant but foreseeing a potential wider margin of resection.
- 3) *Malignant primary bone tumors not responsive to neoadjuvant treatments* (e.g., chondrosarcoma). These tumors usually require, after a local and general staging, a surgical treatment. 3D reconstruction helps to identify noble structures and the level of resection. If customized cutting guides or implants are requested, they should be designed on the latest CT and MRI available. An immediate preoperative Imaging should be repeated in order to confirm the planned resection and reconstruction excluding a local tumor progression. Often tumors belonging to this group are slow growing malignant tumors, for example low grade chondrosarcomas are quite common in the pelvis. This tumor behaviour allows to plan surgery without a predefined schedule depending on chemotherapy or radiotherapy protocols and

therefore, when needed, the design and production of a 3D custom-made prosthetic reconstruction could be performed.

- 4) *Metastatic bone lesions.* Metastatic bone lesions according to the most recent guidelines could be treated as primary bone tumors if they are solitary lesions of a good prognosis primary neoplasm. The multidisciplinary approach and the coordination with the oncologist and the radiotherapist are fundamental in these patients. A 3D planning of metastatic surgery is useful both in case of intralesional treatment or resection. The use of cutting guides or other specific instruments are advisable. The reconstruction could range from traditional techniques (e.g., Harrington procedure) to modular or stemmed revision acetabular implants adapted to the post-oncologic bone defect.

3. COMPUTER ASSISTED TUMOR SURGERY, PATIENT SPECIFIC INSTRUMENTATION AND OTHER APPLICATIONS

Introduced about two decades ago, Computer-assisted orthopaedic surgery (CAOS) is an active research discipline where computer technology is employed to improve the outcome of orthopaedic surgical procedures.

CAOS combines the practice of the orthopaedic surgery with disciplines, such as engineering, computer science, and robotics. CAOS is mostly used in knee implant surgery because of the precision the surgeon gets with femoral and tibial bone cuts. It is also used to navigate acetabular components placement where a correct cup inclination is crucial. CAOS has been recently introduced in musculoskeletal oncologic surgery to enhance surgical precision in the resection of malignant and benign lesions, and in particular in the treatment of malignant pelvic and sacral tumors. This subdiscipline has been called Computer Assisted Tumor Surgery (CATS).

The use of computer technology is applied in each phase: pre, intra and postoperatively in complex musculoskeletal tumor surgery [13], as summarized in Figure 1.

Figure 1. Workflow for CAOS (Computer Assisted Orthopedic Surgery) [14].

Preoperative computer-assisted planning is as important as the intraoperative computer navigation. The better and more detailed the planning, the greater the chance the surgical goals will be achieved when the surgeons implement the planning intraoperatively.

The intraoperative navigation control is followed by a post-operative validation between achieved and planned resection, even performed on CT control of the resected specimen.

The first step is the creation of a digital patient image, most commonly using MRI and CT scan of the anatomical region of interest, showing both precise good bone details and the exact extension of the tumor into the surrounding soft tissues.

The opportunity of merging MRI and CT images with the same spatial coordinates generates fusion images that combine the characteristics of each imaging modality.

At the same time, the possibility to develop 3D images allows to highlight and distinguish the tumor from the normal tissues and its spatial relationship to noble structures (e.g., main nerves or blood vessels).

CAOS also enables the elaboration of functional imaging [positron emission tomography (PET)], which may have the additional benefit of distinguishing the tumor from scar tissue in patients with tumor recurrence who had had previous resection or radiotherapy.

Thanks to the use of different colors in the 3D model, oncology surgeons can obtain a better mental picture of the tumor location and accurately define the surgical resection planes with specific orientation on the virtual patient image.

Preoperative planning also consists in selecting the best surgical approach and defining the location of the noble structures to detect and protect during surgery.

The next step is designing the reconstructive planning after tumor resection. Based on precise 3D resection planning and preoperative CT images, a prosthetic or an allograft reconstruction are possible.

In fact, computer-aided design (CAD) medical engineering software allows surgical simulations of complex tumor resections and the design of custom-made prostheses for bone reconstruction.

In selected patients, CAOS approach facilitates a precise planning and the execution of technically demanding joint-preserving tumor resections and reconstructions with custom CAD prostheses in one-step surgical procedure.

The planned resections should have not only clear tumor margins but also the correct orientation to fit a custom CAD prostheses.

Data about the custom prosthesis can be imported into the navigation system. Surgeons can check and modify the design of the custom CAD prosthesis before approving the project to the manufacturer.

Many Authors illustrated the evolution and clinical results of the CAOS technique at their institution [14, 15].

Wong and Kumta described the largest series of patients [15] with the longest follow-up of at least 3 years. They suggest that CAOS may be helpful in safe tumor resection and may lead to better functional and oncologic outcomes.

Nevertheless, the time period of CAOS development is still relatively short, thus long-term follow-up studies have not been possible yet.

The potential benefits of using CAOS include potential improved reliability of sizing and positioning joint implants, improved accuracy of reconstructed limb length, improved accuracy of prosthetic component alignment, impact on functional outcomes and implant durability.

On the other hand, an increased time required to perform the operation, an increased hospital costs from the additional equipment, software and surgical times, the need for additional images before surgery (such as CT scan) to provide landmarks for surgical planning are the main points against the use of CAOS.

For these reasons, the CAOS technique should not be used for simple resections, but limited to resections at complex anatomic sites or to more technically demanding procedures after an adequate learning curve.

3.1. 3D Allografts

In addition to intraoperative guidance of bone tumor resections, Docquier et al. [16] and Gerbers et al. [17] reported that the same resection planes could be reproduced under navigational guidance to shape the allograft. A better matching of the allograft to the resection defect will improve host-allograft contact, with less chance of nonunion.

Bone allograft reconstruction is an accepted procedure for the recovery of the original anatomy following a pathological or traumatic defect. The use of bone allograft after bone tumor resection has been described with acceptable results in osteoarticular, transepiphyseal, and intercalary reconstructions.

Despite their high complication rate and their slow incorporation into the host bed, biological massive allografts are recommended for great defects such as traumatic or pathological defects of the pelvis. Clinical reports suggest that this approach preserves the long-term bone stock and limb functionality. Furthermore, long-term follow-up studies support and promote the use of allografts instead of prosthetic implants, especially in younger patients.

The selection of the closest anatomical match between the host and the donor is crucial in order to avoid alteration of the joint kinematics and load distribution, leading to articular fractures or joint degeneration.

The bone banks provide bone allografts that are usually collected based on manually measuring anatomical dimensions. In this case, the selection of the bone allograft occurs according to size and shape evaluated on X-ray images between donors and patients.

The use of a CT based registration at the bone bank allows a more accurate comparison between donor and host and therefore a more appropriate selection of the best fitting allograft than the radiograph-based method.

Ritacco et al. [18] described the three steps to obtain a three dimensional virtual bone models from host to donor: *image acquisition*, *image segmentation*, and *3D bone reconstruction*.

A CT scan is generally used for *image acquisition* with identical protocols in host and donor.

Image segmentation is a process, using a specific software that makes the images obtained easier to analyze. The bone after the segmentation process is isolated from the other tissues and structures such as muscles, fat, and skin.

The result of image segmentation is a set of segments or a set of contours extracted from the image that collectively covers the entire 3D bone model, which can be modified to create 3D reconstructions. This tool allows to determine a match by overlapping the host with available donors.

The selection criteria of the graft for a pelvic reconstruction are usually based on the correspondence of the pubis and sacroiliac joint and the acetabular size.

Moreover, this optimal handling of the bone bank limits a potential waste of bone allografts.

After this process, the resection planes might be defined preoperatively. The use of specific softwares allows to transfer the target plane coordinates from the patient to the allograft in order to exactly recreate the same bone gap of the resected tumor.

Furthermore, the support of a navigation system ensures an intraoperative resection of the whole tumor volume with a tumor-free margin and avoids the creation of important gaps at the graft-host junction that could potentially interfere with union and stability. This system also allows to prepare the allograft simultaneously by another surgeon or before tumor resection, since the planes were defined preoperatively. Therefore, the operating time results significantly reduced.

The procedure is even more accurate having the opportunity to simulate and navigate surgery with prototypes. Using a 3D plaster printing based on the CT data, it is possible to define the best reference points and their relationship with resection planes.

3.2. Intraoperative Procedures: 3D Computer Navigation - Patient-Specific Instruments

Custom pelvic prostheses are used to reconstruct the bone defect following complex pelvic bone tumor resection. CAOS allows the engineers to design and tailor-made an implant that matches exactly to the anticipated bone loss after tumor resection. However, the degree of fitting of the custom implant greatly depends on the ability of the surgeons to reproduce intraoperatively the resection as planned.

Pelvic tumor surgery is challenging because of the complex bony anatomy and the close proximity to pelvic organs and neurovascular structures. Accurate resections with wide margins are the most important prognostic factor in managing pelvic bone tumors.

A local recurrence rate of up to 70% is observed after a marginal resection, and 92% after an intralesional resection [19].

To date, three modalities are possible to perform free margin resections and the closest to pre-operative planning: free-hand resections, 3D computer navigation and patient specific Instrument (PSI).

Free-hand resections are certainly the least accurate, despite the surgeon can train on plastic three-dimensional models printed on patient image data.

In recent years, intraoperative 3D navigation and PSI guides have been described with good results.

3D Printing and PSI Development

Rapid prototyping (RP), whether CT or MRI based, allows to create quickly and precisely 3D devices that help oncologic surgeons to study the shape of neoplasms and tailor surgical solutions.

There are six main processes to obtain physical objects via RP: stereolithography (SLA), selective laser sintering (SLS), fused deposition modeling (FDM), laminated object manufacturing (LOM), electron beam melting (EBM), and inkjet printing.

An intraoperative alternative to computer navigation is Patient-Specific Instrument (PSI). Following the previous use for total knee and hip arthroplasty, for pedicle screw insertion and for corrective osteotomy, PSI has recently also been adapted to bone tumor surgery.

The PSI is a customized tool, designed to have bone-specific contact surfaces aiming to guide a saw or a drill into the desired resection planes or positions. These cutting guides are designed on the basis of patient 3D reconstructed imaging and computer-aided design (CAD) software, allowing surgeons to plan surgeries based on the patient's unique anatomy. The blocks of the PSI consist of three components: (1) a surface of contact, that conforms to the footprints contour predetermined by the surgeons, so that the blocks could be positioned consistently near the site of the planned resections without translation; (2) three-planar cutting slot in the blocks, based on the unique orientation of the resection planes defined during virtual simulation in the software; (3) cylindrical guides for the insertion of Kirschner wires to fix the PSI to pelvic bone after correctly positioning the PSI. In addition, PSI provides calibration marks to control over the cutting depth to prevent a soft tissue tear by the saw. These marks represent the distance along the associated direction line measured between the outer edge of the PSI and the deepest bone structure to be cut.

Following surgeons' indications about the surgical approach or exposure, the nearby soft tissues, the defined position and the direction for the placement of PSI, the engineers combine the different components of PSI and create an unique contact interface between the PSI and the host bone.

Orthopaedic surgeons could also practice and familiarize with the proper placement of the PSI on pelvic bone models, fabricated on a 3D printing machine, before approving the final design. The final product is made of a thermoplastic material, with high chemical resistance and high tensile strength, stable to temperatures up to 130°C and thus sterilizable for the use in the operating theatre.

Intraoperatively, surgeons can generally use a standard surgical approach and soft tissue dissection. A possible limit to the technique might be the need for an adequate exposure of the bone surface to optimally fit to it without interfering with soft tissues (ligaments, muscles insertions, etc.). However, Gouin [20] showed that PSI requires only a limited extra bone exposure (less than 10 mm).

Comparing free-hand cutting of pelvic bone tumors with PSI cutting, a significant difference was demonstrated [7]. In fact, free-hand cutting is not accurate enough to ensure wide margins: the errors on the desired safe margin averaged 5.3 mm, with a standard deviation ranging from 2.7 to 5.3 mm among the experienced surgeons, and two resections out of twelve were intralesional. Instead, PSI enables the surgeon to intraoperatively replicate the planned resections with a very good cutting accuracy. Wong et al. [21] reported a millimetric accuracy during a PSI-assisted bone tumor resection of the femur. Khan et al. [22] also investigated bone-cutting accuracy and reported a 2-mm location accuracy during a PSI-assisted multiplanar resection on a cadaveric femur.

The observed level of accuracy suggests that a 5-mm safe margin should be sufficient to obtain clear surgical margins when using PSI. This decrease in the level of desired safe margins allows to perform resections closer to the tumor boundary, offering the possibility to

preserve for example the sacroiliac or the hip joint, a specific portion of a supporting bone, muscle insertions, or nerve roots.

Similarly, a recent cadaveric study compares navigation-assisted and PSI techniques in simulated pelvic bone resections [23]. The mean average deviation error from the planned resection was not different for the navigation and the PSI groups: in both techniques it was less than 2 mm. The mean time required for the bone resection in the navigation group, instead, was significantly greater than that in the PSI group. In fact, Cartiaux [24] showed a similar trend. In this study, the time required for a pelvic resection was 49 minutes for navigation assistance versus 6.9 minutes with PSI assistance.

The increased operative time in the navigation group can be due to the time required for the placement of patient's tracker, system calibration and image-to-patient registration prior to the navigated bone resections. In addition, surgeons have to manually control the direction of the sawblade for the resection under visual guidance on the navigation display, as the existing navigation system does not support a navigated saw.

The greatest risk of PSI is the wrong positioning of its components on the bone surface that leads to a complete lack of precision during the bone-cuts. Further studies are needed to investigate how much bone contact surface is necessary for an accurate placement of the PSI.

According to the actual results, the PSI can be performed safely and provides a good cutting accuracy.

The intraoperative use of the PSI appeared to be quick and easy-to-handle and to require minimal operative setup.

3D Computer Navigation

Computer Navigation is a passive system of image-guided techniques that provides a real-time, interactive, 3D digital map of a patient's anatomy.

A process called "registration" allows to associate the patient's imaging information and anatomical landmarks using an intraoperative navigated device.

This procedure increases spatial accuracy during dissection, surgical resection and instrumentation through a continuous control of images by the surgeon on a video monitor.

Image-based intraoperative computer navigation is currently utilized in craniomaxillofacial tumor surgery, and several studies have demonstrated that the computer navigation technology can improve the precision of various orthopaedic surgical procedures, such as vertebral pedicle screw insertion, joint arthroplasty, and trauma surgery.

Krettek et al. [25] and Hufner et al. [26] have been the first reporters of the use of CT-based navigation in pelvic and sacral tumor resection. They used navigation tools to guide the orientation of osteotomies during surgery and concluded that computer-assisted surgery is a potential method to increase the accuracy in tumor resections involving anatomic and surgical complexity.

In the following years, several centers started reporting the clinical applications and the results of computer navigation and CAOS in orthopaedic oncology.

The first interesting results were obtained by Cartiaux and al., with simulation on plastic pelvic models. They affirmed that the probability for an experienced surgeon to obtain a 10-mm surgical margin with a 5-mm tolerance above or below was only 52% (95% CI 37–67). Also, the degree of host-graft contact for reconstruction was found to be poor.

This group went on to demonstrate in another experimental study that cutting accuracy was significantly improved with computer navigation guidance [27]. In a simulated sawbone model, the error of navigated cutting was only 2.8 mm, whereas that of the non-navigated group was 5.2 mm.

Cho et al. [28] confirmed the accuracy of bone resection in patients operated under computer navigation guidance with CT-MR fusion images, allowing easier joint-preserving resection.

The same group [29] also described as navigation-guided resection is possible without CT images, avoiding the exposure to radiation. Direct patient-to-MRI registration could be obtained during surgery by registering the preoperatively placed fiducial markers (absorbable pins).

Li et al. [30] and Aponte-Tinao et al. [31] described their early results of multiplanar osteotomies around bone tumors using the CAOS technique. Better limb function is achieved after reconstruction if unaffected bone and soft tissue structures are retained.

The source of errors in using CAOS systems is primarily represented by mismatches between the pre-operatively acquired images and the real-time intraoperative patient anatomy. Consequently, the most recent process optimization strategies have focused on acquiring patient imaging intraoperatively through CT or MRI. Even without the intraoperative imaging, navigated accuracy errors of less than 0.5 mm are routinely reported [32].

The increase of the operative time and costs are relevant related issues.

Further studies are required to investigate the cost-effectiveness of navigational procedures, even if comparing it to conventional surgical techniques is difficult due to the low number of patients in the actual case series. While it is expected that the additional time will decrease as surgeons become more familiar with navigation procedures.

Another important limitation is the ability to store accurate image-to-patient registration only concerning the bone. Soft tissues do not appear the same compared to the preoperative virtual images. Consequently, computer navigation allows surgeons to perform accurate bone resection, although soft tissue resection still requires a conventional surgical technique.

4. THE RECONSTRUCTION

Tailored solution are not a novelty in orthopaedic surgery, although not involving 3D. During pioneer years, THA have been built following silicone moulds [33] with disastrous results [34]. Nevertheless, custom made implants have been extensively used in hip [35], knee [36] or humerus [37] showing good outcomes.

Oncologic surgery soon made the most with 3D printing, starting with maxillofacial surgery and neurosurgery, but involving just later most of the other surgical specialties [38].

Orthopaedic oncology has an historical background of custom made implants; in fact, the first custom made implant for limb salvage procedure had been implanted in Wien in 1975 [39]. From the early 90s the use of custom made prostheses began to be commonly accepted [40].

Orthopaedic oncology received many benefits from 3D technologies, especially in pelvic surgery where the increasing use of 3D printing gave the possibility to build custom made implants in an easier and (theoretically) less expensive way.

In literature several case reports and small series are reported [41]. Clavicular, scapular, vertebral, knee and pelvic implants have been described [42]. Virtually any kind of anatomical site could be reconstructed with 3D custom implants for bone or soft tissue tumors, but pelvic is the elective one. Custom made implants in orthopaedic oncology are nowadays a reality in surgical reconstruction of massive periacetabular defects. As previously described, pelvis has a complex 3D anatomy and very important close neurovascular structures. Moreover, being the fulcrum of high forces, implants with the highest probability of ingrowth are the most suitable for long term survival. 3D printing permits easily to add pins, to fit short stems in case of poor bone quality, to guide screw holes, till to foresee screws length. All these features allow, in selected cases, to merge ideal qualities of bespoke shape with high-tech surfaces, in order to minimize the limb loss of function.

Nevertheless, custom made implants are a small part of global reconstructions. Still highly expensive, they need to be implanted in super-specialized centers, with a solid environment of clinicians, surgeons, engineers, and manufacturers. Postoperative care as well needs to be tailored on the patient. When a custom made component is planned and implanted in an oncologic patient, it is the result of a strong cooperation and a solid workflow.

Choosing a custom made implant presents several benefits that may lead to relevant advantages for the surgeon and subsequently for the patient.

- 1) *Surgical margins.* The choice of a custom made implant permits to clarify preoperatively surgical resections, magnifying the chance to obtain adequate surgical margins.
- 2) *Surgical time.* Preoperative planning, with predetermined screw length, permits an easy-to-fix implant. Custom made cutting guides or navigation add further advantages. The combination of these two techniques potentially shortens surgical timings, preventing infections and improving general clinical conditions in high complexity patients. A shorter surgical time means frequently lower blood loss and a better recovery for the patient. In addition, a shorter surgical time reduces the cost of surgery.
- 3) *Reconstruction quality.* 3D printing technique permits highly congruent implants that improve significantly bone-metal interface, creating a wider surface to promote integration. Recent studies described the functional improvement and the lower revision rate in comparison to older techniques for 3D custom implants [43]. Moreover, finite element analysis have been used [41] to evaluate the different behaviour of implants, in order to identify more stressed zones and to use the more technically efficient design.

A biomechanically efficient design of 3D printed components can obviate to those situations where muscular forces are modified due to extensive resections.

A shorter surgical time, wider margins with lower recurrence rate, lower revision rate, and a faster recovery can improve the Quality of Life (QoL) of the patient and determine less expensive global costs counterpointed to an expensive implant.

On the other side, there are many problems that may affect significantly the use of 3D implants

- 1) *Learning curve.* Resection of pelvic tumors is highly demanding from a surgical point of view. Few centers treat a sufficient number of cases to train skilled young surgeons. The importance to be precise and safe is even more requested in pelvic surgery. Moreover, computer assisted resections need further skills that are partially independent from specific oncologic surgical abilities [44]. Nevertheless, this problem affects globally pelvic oncologic surgery and not specifically 3D assisted surgery.
- 2) *Intraoperative resection changes.* This is the main topic to explore when using a custom implant. In fact custom implants works properly to fill a predefined bone loss. Some problems may emerge if a wider resection is needed. If preoperative imaging is done as closer as possible to the interventions, very few intraoperative changes are expected. In most of the cases intraoperative changes are probably due to a lack of accuracy in the preoperative planning more than an effective problem with 3D printed implants. In some cases the implant could be adapted without compromising the final result. In extreme cases, it would be better to convert the reconstructive procedure to “traditional” solutions (hip transposition, allograft, reconstruction cages).
- 3) *Routine use.* It is important to keep in mind that the use of custom 3D printed implants it is not an every-day solution. One problem is the effective time needed to properly plan resection, design, print, and sterilize the implant. In rapidly growing, poor responding masses, like in some cases of malignant soft tissue tumors involving the bone, a custom made implant could not be the best option. In fact, during the whole design and manufacturing time, tumor may grow putting at risk not only the effectiveness of the implant but the feasibility of limb salvage as well. In some other cases (i.e., fractured metastatic patients) the patient may not have a real QoL improvement from a custom implant. Life expectancy, pain control and residual function have to be carefully evaluated to choose the best treatment option. Case centralization in highly specialized center is the best way to control and use in the proper way all the existing techniques.
- 4) *Costs.* A 3D implant requires a huge organization. 3D printing, although its enormous expansion during these years, is still expensive. The entire organization, from Computer Assisted Drafting (CAD) till physical manufacturing of the definitive implant, involves many people. Sometimes cutting guides are printed with SLS or FDM, while EBM printers are used for the implant. Additional intraoperative navigation increases the costs. Nevertheless, no cost-effectiveness [45] studies are available to support one option against the others.

Like many other innovations, 3D printing implants seems to be very promising and they could make a radical difference in complex reconstructive cases.

3D printed implants and global planning could substantially help the surgeon. Like many others, these technologies have some limitations too.

- 1) *Presence of previous metal implants:* metal implants lead to artifacts. Either if diamagnetic steel, titanium or CrCoMo, all metal implants are quite incompatible with 3D printing implants. Advanced MRI and CT scanners, even if with metal signaling suppression, do not have the sufficient detecting power to avoid completely

the scattering phenomenon [20]. Nevertheless, 3D printed specimens could be used to preoperatively evaluate and to explain to the patient some difficult situations, such as complications after a previous surgery (heterotopic ossifications, failed synthesis, etc.). New radiotransparent implant (PEEK, composite carbon fibers-PEEK) are recently available. Their potential interference with navigation systems or 3D planning softwares has yet to be studied [46, 47]

- 2) *Technical feasibility*: to allow good quality of all procedures, good quality images are mandatory. If neither narrow slice CT scan nor MRI could be performed due to technical problems, no 3D reconstruction/planning could be hypothesized.
- 3) *Potential metal allergies*: to our knowledge, there are no reported cases of allergic reactions to custom metal implants in literature. These implants, being usually printed in titanium alloys, have very low allergenic potential; titanium is commonly used in metal allergic patients. Nevertheless, in highly reactive patients with documented allergy (i.e., patch tests), the use of a metal printed implant has to be carefully assessed.

5. TECHNICAL TIPS FOR CUSTOM-MADE PELVIC RECONSTRUCTIONS AND CLINICAL CASES

- If the posterior acetabular column is free from neoplastic disease, it is still possible to perform an extraarticular resection of the hip joint supported by PSI cutting guides or intraoperative navigation. A geometrical triplanar periacetabular osteotomy (“Ganz osteotomy”) preserving the posterior column could be planned to allocate the acetabular custom-made prosthesis (clinical case in Figures 2-5). An intact posterior column allows to reach a sitting position sooner. Avoiding the posterior interruption of the pelvic ring the primary stability is increased, even if associated to a pubic resection. Postoperative rehabilitation could be faster, achieving 90° of flexion of the hip in the first weeks. The implant as well is subjected to limited stresses when the patient seats, still existing a “bone buttress” than counteracts shear forces.
- *The choice of materials*. A wide range of materials is available at present. Usually the bulk structure of a pelvic custom-made prosthesis is based on Titanium or Titanium alloys. The bone-prostheses interface is usually primarily fixed with screws but an integration is fundamental for the secondary or long term stability of the implant. Different porous or bioactive materials are available (e.g., Trabecular Titanium, Trabecular Metal, hydroxyapatite ...) [48–50] to obtain bone ingrowth at the contact surface. The introduction of these materials is quite recent but they are widely used in general orthopaedics and in orthopaedic oncology and there is no evidence that these materials could increase the recurrence rate. Porous materials could be also used to reattach tendons and muscles in their anatomic position to improve final function but the contact with nerves, vessels, and visceral pelvic organs should be avoided. An accurate planning of the position of porous material reattachment areas is mandatory in the design phase. Silver coating [51–53] has been demonstrated useful to decrease local infection rate in tumor megaprotheses but there are only preliminary results about pelvic reconstructions.

- The fixation with the residual bone is fundamental but strictly conditioned by the tumor extension. As a general rule a stable primary fixation with the sacrum or the iliac wing using screws or short stems and porous surfaces could be obtained (clinical case in Figures 6-9). The pubic fixation is still debated. As described by several Authors [54, 55] only a minor amount of load is conducted through pubic symphysis during walking and standing activities. As a further confirmation, trauma surgery showed how pubic fixation is seldom strictly required. Nevertheless, pubic fixation may improve primary stability in the early postoperative phases but it cannot be considered a reliable site for an exclusive fixation. An ingrowth fusion with a porous or bioactive contact surface is possible at distance, to improve overall stability and eventually decrease forces acting on ischial and iliac contact areas. Generally no worries should be made in case of a secondary failure and the patient should be informed about this potential event.
- The hip joint articularity is an extremely debated topic. The use of a retentive snap cup or a double mobility cup generates a different range of motion and consequently a different stability of the components. Whether to have a restricted or a free articularity can generate an advantage from a biomechanical point of view has a complex answer. Different aspects should be considered: soft tissues and muscles excision, nerve resection, primary bone stability, and the type of femoral implant. Recent studies showed that a double mobility cup can prevent joint dislocation without restricting the range of motion and without increasing stress forces on the acetabular area.

Figure 2. Girl 13 years old, biphasic synovialsarcoma of the hip joint. Chemotherapy was administered according to current protocols.

Figure 3. A custom made TiAlV alloy prosthesis was realized with Trabecular Titanium bone- implant interfaces and fixation with screws to the ilium, ischium and posterior column. Porous surfaces and holes were added in correspondence of main muscle groups attachments (glutei muscles and rectus femoris).

Figure 4. An extraarticular resection of the hip joint involving femoral head till the greater trochanter was necessary: a geometrical triplanar periacetabular osteotomy (“Ganz osteotomy”) preserving the uninvolved posterior column was planned and performed using PSI cutting guides.

- The removal of the resected neoplastic lesion and the insertion of the custom-made prosthetic components should take into consideration noble structures (nerves, vessels, visceral organs,...) and soft tissues. Cutting guides and other PSI devices are realized taking into consideration how to avoid or not to stretch too much major nerves and vessels. The removal of a resected pelvic tumor is as critical as the prosthesis insertion. The integrity of the tumoral mass should be preserved for oncologic purpose. The insertion of the prosthesis and all the instruments to provide its fixation should be respectful of the anatomic structures.

Figure 5. Postoperative Xray control of the reconstruction. The patient started to walk one week later, and with partial load bearing two months later. At 3 months, full weight bearing was possible, unaided at 5 months. At one year of follow up, the patient was free from disease and was walking without limping or pain. Monopodal load bearing on the operated side was possible without Trendelenburg sign.

Figure 6. A-B Boy, 17 years old. Osteoblastic osteosarcoma right hemipelvis. Pre-chemotherapy MRI showing the extension of the tumor and the involvement of sacroiliac and hip joint. Post-chemotherapy staging showed a reduction of the tumoral mass in the soft tissues but confirmed the presence of neoplastic disease in the bone structures previously involved.

Figure 7. The resection of the tumor and the reconstruction were studied with 3D planning CA based softwares using CT and MRI. A Titanium hemipelvic endoprosthesis was realized with Trabecular Metal (TM™) plates at the sacral and pubic bone-prosthesis interfaces.

Figures 8-9. The prosthesis was fixed in the sacrum and pubic rami with screws. The glutei and rectus femoris muscles were sutured to the implant using special TM holes. Full-weightbearing was obtained after 6 months. Signs of radiologic bone ingrowth were evident 2 months post-operatively.

CONCLUSION

3D customizing is an innovative and expanding field in orthopaedic oncology and especially in pelvic lesions. Preoperative study, resection, intraoperative navigation and custom made implants are nowadays viable options for treating pelvic tumors.

All these procedures should be performed in high specialized and selected centers due to technical and learning curve reasons.

A continuous constructive confrontation is advisable among the orthopaedic surgeons of the main reference centres and the engineers of the producing companies in order to improve the implant design and overall the patients' function and QoL.

ABSTRACT

Surgical resection is an optimal curative approach to hepatocarcinoma. When transplantation is not feasible, hepatectomy is the first choice to effectively treat HCC. The 5-year overall survival for the disease stages that benefit from this approach, ranges from 50 to 70%. Unfortunately, only 20-30% of patients are eligible for curative intervention. Moreover, the 5-year-recurrence rate after surgery is close to 70%.

Over the last decades, the attempt to reduce recurrence rate, together with a more thorough understanding of the mechanism underlying this phenomenon has lead experts to ask themselves what the best surgical procedure could be. Defining the right extent of the resection is often difficult and unequivocal guidelines have yet to be established. Currently, most international guidelines suggest that the anatomic resection (AR) of a liver segment may allow the removal of the segmental portal bed, preventing microvascular invasion and satellitosis which may be the cause of intrahepatic metastasization (currently ranging between 20 and 70%). Nevertheless, many reports have shown a similar rate of local recurrence (almost 15%) in cases of parenchyma-sparing resection (PSR), where the cancer nodule is removed regardless of the portal segment extension. A recent meta-analysis showed no significant differences in

* Corresponding Author's Email: simone.famularo@gmail.com.

recurrence rate in the two procedures (RR 1.28, 95%CI: 0.59-2.76; p :0.53). No clear advantages can be proven in terms of overall survival, either: the 5-year overall survival rate is 64.9% for AR and 61.1% for PSR. Moreover, PSR was proved to be a safe and oncologically correct technique for cirrhotic patients, for whom preserving as much parenchyma as possible is mandatory to reduce the impact of postoperative liver failure or ascites.

In this chapter, we will focus on the indications to surgery in HCC, on how to perform a liver resection, and on the different indications to the two main surgical approaches to hepatocellular carcinoma. We will discuss long-term outcomes; different theories on the causes of recurrence after resection, and how this evidence could possibly lead to an extension of the indications to a surgical curative approach in primary liver carcinoma.

1. INTRODUCTION

Hepatocellular Carcinoma (HCC) is one of the 5 most common malignancies worldwide and the third most common cause of cancer related mortality, accounting for 500,000 deaths globally every year. Although more common in East Asia, the incidence of HCC is constantly increasing in the Western world [1]. Hepatic resection is the first-line therapeutic option and is accepted as a safe treatment, with a proven impact on prognosis and with a low operative mortality, result of the recent innovations in surgical techniques and perioperative management [2]. These advances have improved the outcomes of hepatic resection for HCC, reducing operative morbidity and mortality [3]. However, only 20 to 30% of HCC patients can be candidates to surgical resection because of a poor hepatic reserve function, either caused by underlying chronic liver disease or by HCC multifocal distribution. Although hepatic resection is considered to be a curative treatment for hepatocellular carcinoma, HCC recurrence rate after surgery is quite high, approaching 50% in the first 3 years and reaching 70% in the first 5 years after curative resection [4, 5]. Thus, long term results after surgery remain unsatisfactory. This poor prognosis is commonly alleged to the high incidence of intrahepatic metastasis and of multicentric de novo HCC [6] which develop in accordance with the precancerous status of the remnant diseased liver [7]. With respect to intrahepatic recurrence, macro-portal invasion and intrahepatic metastasis were considered to be the strongest risk factors to affect postoperative prognosis.

However, the role of the different recurrence mechanisms still needs to be clarified. Previously, portal vein dissemination caused by the spreading of HCC cells through the portal vein and its branches was considered the main route for intrahepatic metastasization. This led to the notion that anatomical resection, whose limits are defined by the area of the venous, may prevent intrahepatic metastasization of HCC [8, 9, 10]. Based on this premise, Makuuchi et al. [11] described a correct anatomic resection as the systematic removal of the tumor-bearing hepatic segment confined by its portal tributaries. From a theoretical standpoint, this procedure may be effective in preventing intrahepatic metastasis of HCC. Based on the portal blood flow dissemination theory [12], some authors [13, 14] have used AR for HCC, showing oncological and survival benefits for AR over non-anatomical resections (NAR). However, their results have been debated and no definite conclusion can be drawn from them.

Other authors have reported that AR may prevent hepatic recurrence and prolong survival [15]. In their systematic review of 18 observational studies involving a total of 9036 patients,

Cucchetti et al. [12] showed that AR provided a better 5-year overall survival (OS) and disease-free survival (DFS) rate than NAR. Other meta-analyses such as the one by Zhou et al. [16] reported similar results. This data reinforces the theory that AR may reduce the risk of intrahepatic metastasization through portal flow. In a large research project based on Japanese national data analysis, Eguchi et al. [8] also proved a higher RFS rate in AR than in NAR, but a significant statistical difference has not been observed for patients with an HCC larger than 5cm. Despite the advantages shown by these studies, AR can be more difficult to perform and carries more risks than NAR for patients with a low preoperative liver function (e.g., those with cirrhosis). Generally speaking, a larger part of liver parenchyma is resected in AR than in NAR, leading to an increased risk of intraoperative bleeding and to a longer operation time. In clinical practice, surgeons tend to prefer AR when HCC patients display a good liver function, a small-sized tumor, and no cirrhosis.

The evidence of HCC recurrence occurring even in cases treated by hepatic resection and liver transplantation lead to the development of new theories on the pathogenesis of intrahepatic metastasization. According to this new insight, HCC metastatic cells may spread by first migrating through the tumor blood flow (TBF) and then rehome to the remnant liver [17, 18]. Sakon et al. [19] defined three different patterns of intrahepatic recurrence of HCC as detailed below. Local Intrahepatic Metastasis (IM) (1): HCC recurrence around the tumor by direct spread of the tumor through portal blood flow or venous drainage; Systemic IM (2): HCC recurrence caused by circulating tumor cells (CTCs); MC (3): multicentric HCC recurrence caused by de novo development of HCC. HCC circulating tumor cells have been detected in 81-88% of patients at the time of surgery [20]. Early circulating tumor cells are thought to be spread by portal vein branches [21]. AR aims to resect the liver and the supplying portal vessels respectively in accordance with Couinaud's segments. Thus, theoretically, AR should resect micrometastases (MMTs) within the anatomical segment and reduce the risk of recurrence. It is therefore reasonable to postulate that AR would be more effective than NAR in clearing MMTs and circulating tumor cells, thus decreasing local recurrence (LR) caused by "nearby" MMTs, but not distant recurrence (DR).

Nonanatomic resection (NAR) focuses on achieving a margin-negative liver resection without considering Glisson's pedicle distribution. Because of the high prevalence of underlying liver conditions such as chronic hepatitis and cirrhosis, NAR is often preferred for patients with hepatocellular carcinoma, since it allows sparing of as much liver parenchyma as possible [22]. A cirrhotic liver has a very limited capacity for regeneration and this affects long-term prognosis, which is benefited by parenchyma sparing resections.

Due to the unbalanced distribution of AR and NAR, it was difficult to reach a consensus concerning the advantage of AR in previous studies. Recent studies have failed to confirm the benefits of AR [23, 24] on survival. Okamura et al. and Marubishi et al. [6, 25] have questioned the advantages of AR and showed the incidence of HCC recurrence to be similar on comparing AR and NAR groups. Thus, the effective superiority of AR compared to non-anatomic resection (NAR) remains controversial. Therefore, surgeons must maintain a balance between radical surgery and the need to preserve the function of the remnant liver, which is the focus of the dispute between AR and NAR. No clear advantages could be shown for either of the two techniques in terms of overall survival: the 5-year overall survival rate was 64.9% for AR and 61.1% for PSR. To date, no randomized controlled study has compared outcomes of these two resection methods. The main problem that surgeons face while operating on patients with cirrhosis is balancing the need to achieve a radical

intervention while simultaneously preventing the development of postoperative liver failure that could ensue from the removal of too much liver parenchyma. This problem is the basis of the dispute between AR, a theoretically more radical procedure from an oncologic point of view, and NAR, which reduces the risk of postoperative hepatic failure. The oncological advantage of AR has been actively studied and discussed for decades. The available data is insufficient to prove the prognostic advantage of AR due to the reasons listed below.

First, the definition and surgical technique for AR are not standardized among institutions. Second, the baseline characteristics vary considerably in previous studies making it difficult to determine the pure prognostic advantage of AR, even by meta-analyses, due to the heterogeneity of the target population. Third, because of the significant differences in the preoperative liver function in AR and non-AR populations, a simple prognostic comparison cannot be free from selection bias.

In this chapter we will briefly focus our attention on the surgical indication in HCC, on how to perform a liver resection, and on the different indications to the two main surgical approaches to hepatocellular carcinoma. We will discuss long-term outcomes; the different theories on the mechanisms of recurrence after resection, and show how this evidence could possibly lead to a future extension of the surgical curative approach to primary liver carcinoma.

2. INDICATION TO SURGERY

Hepatocellular carcinoma (HCC) is often associated with liver cirrhosis [26]. As a result, the choice of treatment of this pathology is complex and subject to much debate. There is the need to obtain a radical oncological cure, and, at the same time, to ensure the preservation of as much functioning liver parenchyma as possible, considering that it is frequently already compromised by the underlying liver disease. Liver transplantation is theoretically the only possibility for handling both HCC and liver cirrhosis, but this option is not always viable due to the limited availability of organ donors [27]. Moreover, for patients exceeding Milano Criteria, and therefore excluded from transplant, hepatic resection seems the best chance for obtaining a prognostic improvement, reducing morbidity and mortality rates [28].

Nowadays, the most largely accepted algorithm able to direct HCC therapy is based on the Barcelona Clinic Liver Cancer (BCLC) classification (Table 1) developed and validated by the European Association for the Study of Liver Disease (EASL) and by the American Association for the Study of Liver Disease (AASLD) at the end of the last century [29–31] and constantly updated at consensus conferences [32]. In order to determine the patient's prognosis, this classification takes into account preoperative liver status, based on Child-Pugh class, bilirubin levels, presence of portal hypertension, general physical status and local tumor characteristics [33, 34]. It also provides recommendations on therapeutic options, as shown in Table 2. Liver resection, PEI (Percutaneous Ethanol Injection) and thermal ablation with radiofrequency (RFA) are indicated as radical treatments for early-stage tumors. Patients with multiple, large or macrovascular invasive HCC are addressed to palliative treatments, such as TACE (Trans-Arterial Chemo-Embolization), chemotherapy with new agents or others supportive treatments [30].

Table 1. BCLC classification

<i>Stage</i>	<i>PST</i>	<i>Tumour characteristics</i>	<i>Liver functional status</i>
Stage 0: very early stage HCC	0	Single < 2 cm	No portal hypertension and normal bilirubin
Stage A: early HCC			
A1	0	Single < 5 cm	No portal hypertension and normal bilirubin
A2	0	Single < 5 cm	Portal hypertension and normal bilirubin
A3	0	Single < 5 cm	Portal hypertension and abnormal bilirubin
A4	0	3 tumours < 3 cm	Child-Pugh A-B
Stage B: intermediate HCC	0	Large multinodular (single tumour > 5 cm or 2-3 tumours of which at least one is > 3 cm)	Child-Pugh A-B
Stage C: advanced HCC	1-2	Any tumour with radiological evidence of vascular invasion or extrahepatic spread	Child-Pugh A-B
Stage D: end-stage HCC	3-4	Any	Child-Pugh C

PST: Performance Status Test

Table 2. Treatment schedule according to BCLC classification

<i>Stage</i>	<i>Treatment intention</i>	<i>First/Second Line treatment</i>
Stage 0	Radical	Surgical resection
Stage A: early HCC		
A1	Radical	Surgical resection
A2	Radical	Surgical resection → OLT/Percutaneous treatment
A3	Radical	OLT/Percutaneous treatment
A4	Radical	OLT/Percutaneous treatment
Stage B: intermediate HCC	Palliative	Trans-Arterial Chemo-Embolization
Stage C: advanced HCC	Palliative	New agents
Stage D: end-stage HCC	Symptomatic	Supportive treatment

OLT: Orthotopic Liver Transplantation

In early stage HCC, both surgery and radiofrequency are indicated as first-line treatments, with certain specifications: patients that present multiple comorbidities, elderly patients and, in wider terms, all patients that cannot tolerate a general anesthesia are addressed to radiofrequency. An increased level of bilirubin, portal hypertension or the presence of multiple nodules are also indications to radiofrequency [32]. In selected patients with multinodular HCC, surgical treatment can be associated with intraoperative radiofrequency; this is done, for instance, to achieve radicality on hepatocarcinoma nodules located in anatomically unfavorable positions. Starting from EASL and AASLD recommendations, many local guidelines have been developed by the main liver study groups.

It is universally accepted that, apart from liver transplantation, and consistently with a BCLC treatment schedule, hepatic resection is the best course of treatment for “very early” or “early” stage HCC. Nevertheless, several single-center reports describe benefits from surgical treatment even for patients with microvascular invasive, multinodular or large HCC. Especially for stage B HCC, the lack of indications to a curative treatment strongly contrasts

with clinical practice where, in many centers, patients are addressed to hepatic resection, with a largely demonstrated increase in overall survival (OS) and disease-free survival (DFS) [35-39]. This led to the diffusion of alternative local algorithms, to guide the selection of patients who are eligible to a surgical treatment.

In 2005, Ng et al. demonstrated that even large or multinodular HCC can safely undergo surgical treatment. On a large multi-institutional database of patients treated with hepatic resection in 5 major hepatobiliary centers in Asia, Europe and The United States, they showed a 5-year overall survival of 39% [35]. Ishizawa et al. showed that an adequate patient selection, according to the Child-Pugh class, allows for a dramatic increase in overall survival rates (up to 56%) among Child-Pugh A patients, even in the presence of multiple tumors or portal hypertension [36]. In 2013, Torzilli et al. definitely demonstrated how an update of EASL/AASLD therapeutic guidelines was needed. They conducted a retrospective multicentric survey, showing how, in current clinical practice and in opposition to the existing guidelines, more and more centers recur to surgery for patients with multinodular, large and macrovascular invasive HCC with acceptable short- and long-term results [37]. Almost simultaneously, Bolondi and a panel of experts, proposed a sub-classification of BCLC stage B HCC in order to tailor therapeutic interventions, taking into account the widely emerging data and expert opinions [40, 41]. The staging system was extended as depicted in Table 3.

Taking the lead from this sub-classification, Ciria et al. reported an increase in 5-year overall survival to 62.9%, 28.1% and 15.4%, respectively for B1, B2 and B3-4 stages. They therefore suggested to include this new criteria in the official guidelines [38].

Table 3. BCLC sub-staging

<i>Sub-stage</i>	<i>Child-Pugh score</i>	<i>Up-to-7 criterion*</i>	<i>PST</i>	<i>PVTT</i>
B1	5-7	IN	0	NO
B2	5-6	OUT	0	NO
B3	7	OUT	0	NO
B4	8-9	ANY	0-1	NO

* Up-to-7 criterion combines the number of nodules and the major tumour diameter, with the sum being no more than 7.

To our knowledge, the most recent paper on the subject was published in 2018 by Liang et al. It consisted in a systematic review and meta-analysis of Asian data comparing the surgical approach and TACE in intermediate stage HCC. This publication confirmed once again the superiority of hepatic resection in terms of overall survival, without any significant increase in 30-day mortality rates [39]. Given the complexity of the criteria for the surgical approach and their non-universal acceptance, an update in official recommendations is needed. In the meanwhile, a multidisciplinary evaluation of each single case is desirable and useful, in our opinion, since different specialists are potentially involved in the treatment and follow-up of an HCC patient [42].

3. ANATOMIC RESECTION (AR) AND PARENCHYMA-SPARING-RESECTION (PSR)

3.1. Generalities

Recent technical improvements have made hepatectomy for hepatocarcinoma (HCC) an increasingly safe form of curative treatment. However, the long-term survival of patients remains unsatisfactory due to the high rates of recurrence, estimated between 70 and 80% after 5 years [43, 44]. Recurrence can be intrahepatic or multicentric. While different kinds of treatment may suppress liver fibrosis and thus prevent multicentric recurrence, intrahepatic recurrence seems to be closely related to local vascular invasion, thus making anatomical resection (AR) the best technique to prevent it, from a theoretical standpoint [45].

Microportal invasion and intrahepatic metastasis were once considered to be the most important factors leading to recurrence and were associated with poor prognosis [46, 47]. On this basis, Makuuchi et al. first described AR in 1985 [48]. The procedure is based on the systematic removal of a liver segment with its tributary portal branches and should theoretically allow the elimination of intrahepatic micro metastasis improving patient survival. The long-term outcome after resection of hepatocellular carcinoma, however, is also influenced by factors related to the characteristics of the tumor and by the underlying liver disease.

Today the choice between anatomical resection (AR) and non anatomical (NAR) resection for HCC is controversial. From an oncological point of view, AR appears to be superior to NAR, enabling to obtain negative margins and leading to a better 2-year recurrence rate for high grade aggressive tumors, as it permits the removal of satellite lesions and microvascular invasion [23]. Moreover, the better control of the vascular pedicle in AR allows for a reduced intraoperative blood loss, leading to a lower rate of postoperative morbidity and mortality [49]. In fact, NAR results in a higher incidence of biliary fistula and infection because of the higher percentage of remnant devitalized liver tissue [7]. To understand the vascular and biliary anatomy of the liver is mandatory for a successful AR. Since HCC usually develops over a background of liver cirrhosis, it is important that anatomical resection be able to clear the tumor and still leave a sufficient amount of liver to avoid postoperative liver failure.

The concept of anatomical resection is based on the division of the liver into segments first described by Healy in 1953 [50] and updated by Couinaud in 1957 [51]. Nowadays, from a surgical-functional point of view, we no longer divide the liver into lobes, according to classic topographic anatomy, but, more correctly, into segments based on portal, arterial and biliary branching. The liver, as proposed by Couinaud [51], is therefore divided into four sectors, each delimited by a branch of the portal vein; sectors are further divided into segments for a total of eight, conventionally indicated with the corresponding Roman number. The projection, on the upper surface of the liver, of the course of the main hepatic vein (the main portal fissure, corresponds to the ideal line connecting the left margin of the cava vein to the bottom of the gallbladder) divides the organ into two hemi-livers: right and left, provided with an autonomous vascular and biliary supply. The two hemi-livers are in turn divided into two sectors from the left and right portal fissures (Figure 1). The right portal fissure corresponds to the course of the right hepatic vein and is projected on an ideal line that from

the right margin of the vena cava points anteriorly to the middle point between the right margin of the liver and the right margin of the gallbladder (Figure 1). The left portal fissure corresponds to the course of the left hepatic vein and is projected on an ideal line that from the left margin of the vena cava reaches the left margin of the liver (Figure 1). Starting from the right lobe of the liver and moving towards the left, you can distinguish:

- The *right lateral sector*: formed by the VII° (above) and VI° segment (below)
- The *medial right sector*: formed by the VIII ° (above) and V° segment (below)
- The *left medial sector*: formed by the I° and IV° segments (lateral) and by the IV° and III ° segments (medial)
- The *left lateral sector*: formed by the II° segment (Figure 2)

Figure 1. Representation on the anterior (a) and inferior (b) surface of the liver, of the portal fissures and of the division in segments: 1) right portal fissure; 2) main or median portal fissure; 3) right portal fissure.

The scientific committee of the International Hepato-Pancreato-Biliary Association proposed the Brisbane 2000 Terminology of Liver Anatomy and resection [52] to define a universal terminology with which to refer to liver anatomy. According to this terminology, first the liver is divided into two parts, the main liver and the caudate lobe (called I° segment by Couinaud). Then the main liver is divided into the right and left liver. The practical applications of this subdivision is proven by the fact that this terminology has gained wide acceptance removing most of the confusion that existed in the past.

Figure 2. Subdivision of the liver into segments according to Couinaud.

To perform a precise anatomical liver dissection it is necessary to accurately identify the segments and the portal fissures during resection. Different methods of segment identification are employed both in conventional hepatic surgery and in laparoscopy. The most widely tested methods are the tattooing method [48, 53] and the Glissonian approach [54, 55], which is especially simple to perform. Other techniques have been experimented; some Authors inject intravenous indocyanine green after clamping the Glissonian pedicle to better define the resection margins [56]. The aim of this section is to describe the various techniques currently used to perform an anatomical resection of the liver in the presence of HCC.

3.2. Anatomical Resection

As already described, anatomical resection refers to the resection of the tumor-involved segment or section, together with its portal vein branch, resected *en bloc*. This approach includes: left or right hepatectomy, hemihepatectomy, segmentectomy and sub-segmentectomy, sectionectomy and trisectionectomy, based on Couinaud's classification. In sectionectomy, the resection line is defined by a demarcation on the liver surface after ligation of the sectional pedicle and of the trunk of the hepatic vein exposed on the resected surface [42].

3.2.1. Glissonian Approach

The approach to the Glissonian pedicle has enabled us to obtain new knowledge of liver anatomy which lead to an improvement of surgical techniques. This approach starts with an extra fascial access to the hepatic hilum. The secondary Glissonian pedicles are taped and ligated at the hepatic hilum without parenchyma dissection. Dissection starts above the hilar plate so that the surgeon does not have to take into account possible artery and bile duct anatomic variations. Tertiary branches can be approached through the hepatic hilum or

through the liver parenchyma at the margin between segments [57]. The Glisson capsule is made up of connective tissue covering the peduncle, which in turn contains the hepatic artery, portal vein and bile duct. The Glisson capsule is connected to the liver capsule and to the hepatoduodenal ligament forming a thick plate on the inferior face of the liver, which is referred to as the “hilar plate.”

The first dissection of the hepatoduodenal ligament elements during hepatectomy was performed around 1950 and the procedure was defined as the first hepatectomy with controlled method [58]. By contrast, a few years later, other Authors started dissecting the liver parenchyma, approaching and ligating the portal pedicles intra-hepatically [59, 60]. These two approaches are recognized as being the basic techniques for anatomic liver resection [61]. Couinaud et al. [62] and Takasaki et al. [54] first reported the Glissonian approach to the hepatic hilus respectively in 1985 and 1986. Couinaud [63] later described three different ways to approach Glissonian pedicles: *the intrafascial*, *the extrafascial*, and *the extrafascial and transfissural approaches*.

The *intrafascial approach* involves a conventional dissection of the hepatoduodenal ligament. Dissection is performed below the hilar plate, making the procedure unsafe, and surgeons have to take into account possible anatomic variations of the hepatic artery and bile ducts. In the *extra-fascial approach*, instead, the pedicle is dissected first through the hepatic parenchyma and then extra-hepatically at the hilum. In the *extra-fascial and transfissural approach* the main portal fissure or left supra-hepatic fissure are opened after dissecting the liver parenchyma, and surgeons can therefore appreciate the direction and distribution of the pedicles that arise from the hilar plate. This procedure involves major hepatic transections along the main portal branches or the umbilical fissure [59, 60]. The extrafascial approach is further separated into the *intrahepatic* and *extrahepatic* approaches depending on the presence or absence of parenchymal destruction. Intrahepatic isolation can possibly lead to unexpected injury of the portal pedicle or hepatic vein, therefore extrahepatic Glissonian pedicle isolation should be considered the ideal procedure [64].

To approach the right Glissonian pedicle the procedure provides that, after cholecystectomy, the cystic plate be dissected. Behind the cystic plate, the right anterior Glissonian pedicle can then be recognized and approached carefully after having detached the hilar plate from the liver parenchyma. Subsequently, the pedicle is completely dissected and clamped to confirm the extension of the area supplemented by its flow. The right, posterior pedicle can then be taped after the main pedicle is. Afterwards, the tape is pulled at the ramification between the anterior and right posterior pedicle. This procedure allows us to evidence the area of altered parenchymal staining after clamping and the site of the neoplasm as confirmed by ultrasound. At this point the pedicle must be ligated and dissected before going further with the liver section [55].

The approach to the left pedicle was first described by Couinaud in 1985 [62]. Dissection starts to the left of the hilus and is then conducted along the ventral surface of the Arantius duct. Finally the pedicle is encircled and clamped. Some liver surgeons have attempted to reproduce these methods in laparoscopy, but, due to the anatomic complexity of the liver and to the inherent limitations of the laparoscopic technique, this has proven difficult. The recent introduction of robotic techniques has enhanced the possibilities of performing minimally invasive liver surgical procedures. Recently, Lee et al. [65] reported a series of 10 patients subjected to an extrahepatic right approach of the Glissonian pedicle by robotic route. Four robotic ports and one assistant port were used. The falciform and ipsilateral coronary ligament

were sectioned, the inferior and posterior sides of the liver freed from the diaphragm and the plane of the inferior vena cava exposed. The liberation of the right liver is achieved through the section of accessory hepatic veins. The selected Glissonian pedicle is then dissected by the extrafascial approach, at the hepatic hilus for the right resections and at the level of the round ligament for medial and lateral sectionectomy.

When resection is first conducted along the right or left side of the round ligament, parenchymal transection is performed to expose Glissonian pedicles. In right posterior sectionectomy, the gallbladder is retracted upwards to expose the hepatic hilus and the portal branches that supply the I° segment, which are sectioned to expose the main portal branches. Once the pedicle has been identified, it is encircled and closed with a laparoscopic clamp. Clamping produces an ischemic demarcation on the line of hepatic transection that is then marked with an electrocautery hook. Finally, an intraoperative ultrasound examination is performed to confirm the location of the neoplasm and the extension of surgical margins.

3.2.2. Indocyanine Green

In hepatobiliary surgery, the fluorescence and bile excretion of indocyanine green (ICG) can be used for real-time visualization of biological structures. Intra-operative fluorescence imaging can be used to identify subcapsular hepatic tumors and to define the limits of hepatic segments. The limits of hepatic segments can be visualized through the injection of ICG in the portal vein or after intravenous injection following the closure of the portal pedicle proximal to the region that has to be removed. This technique enables the identification of liver segments before surgical resection and during parenchymal transection for anatomic resections. Intraoperative fluorescence imaging is able to localize the neoplastic lesion thanks to the biliary secretion disorders that are characteristic of the neoplastic tissue of hepatocellular carcinoma and of the hepatic parenchyma surrounding adenocarcinoma [66].

Fluorescence imaging following portal injection of ICG was used for the first time in 2008 for the identification of hepatic segments [67]. Since then, the technique has been improved by combining a more diluted ICG solution (2.5 mg) to an imaging system able to merge fluorescence images with color images [68]. The concomitant injection of indigo-carmin solution (an organic salt derived from indigo by sulfonation) and ICG can increase the rate of identification of the liver segments, especially in patients affected with cirrhosis or that have undergone previous surgery, where the presence of connective tissue can mask the hepatic surface [69].

In addition to identifying hepatic segments after portal injection of ICG (*positive staining technique*), hepatic segments can also be identified as ischemic areas through intravenous injection of ICG after closure of the corresponding portal pedicle (*negative staining technique*) [68, 70]. Intraoperative fluorescence imaging may also allow us to estimate portal uptake in veno-occlusive regions of the liver during hepatectomy [71].

The use of indocyanine green in localizing the neoplastic lesion in need for removal is also useful in minimally invasive surgery, where the possibilities of inspection and manipulation are limited compared to open surgery. Furthermore, the negative staining technique is particularly useful in laparoscopy where injection of ICG into the portal vein is technically difficult [70, 72]. When the V° VI° VII° VIII° liver segments have to be approached, different difficulties may arise that make it harder to perform the operation in laparoscopy, while intraoperative ultrasound may be difficult due to the impossibility of freely handling the ultrasound probe.

In this regard, Ueno et al. [56] reported a new technique for liver segment identification in laparoscopic surgery. They previously performed a laparoscopic splenectomy concomitant with interventional radiology for hypersplenism to reduce intraoperative blood loss. With this technique the authors tried to overcome the difficulty of dye injection during laparoscopic intraoperative ultrasound. At first they mobilized the liver, then, from the right femoral artery, they inserted a 3 French (Fr) sheath catheter, under the guide of preoperative simulation images. Two other catheters of 3 and 1.9 Fr respectively were inserted into the celiac artery and into the targeted arterial branches. After confirming the perfusion area through arteriography, a mixed dye solution including ICG was injected into the target and the branches were embolized using gelatin particles.

The mixed dye solution was composed of: 2 mL of a diluted ICG solution, 2 mL of indigo carmine water, 1 mL of Sonazoid solution and 1 mL of a contrast medium. As an embolic agent 1 mm of porous gelatin particles were mixed with 3 mL of a mixed dye solution and 10 mL of a contrast medium. At this point about 3 mL of mixed dye solution were slowly injected into the target and the targeted branches were then embolized. When performed under fluoroscopy monitoring, this technique requires a hybrid operating room. Immediately after the injection of the dye solution mixture, visual alterations can be observed on the surface of the liver, along with ICG fluorescent margins, that define the intraparenchymal cutting line.

3.3. Parenchyma Sparing Liver Resection

Liver resection often represents the treatment of choice for both primary and secondary liver malignancies [73]. Depending on tumor location, dimension and diffusion major resections may be required to achieve an adequate oncologic result. Volume of remnant liver is crucial to avoid postoperative liver failure, especially in cirrhotic patients or in patients submitted to neoadjuvant chemotherapy. In order to reduce the substantial morbidity and mortality associated with major liver resections, attention has focused on the technical possibility of sparing as much liver as possible while aiming at achieving, at the same time, an effective oncological result.

A better knowledge of tumor biology and of its influence on local recurrence and survival, and the development of intraoperative ultrasound skills, constitute the basis of the so-called “parenchymal sparing liver surgery.” The term parenchymal sparing resection (PSR) encompasses a wide range of resections, ranging from non anatomical, small, wedge resection to more complex non-anatomical atypical resections.

3.3.1. Preoperative and Intraoperative Planning

The prerequisite for PSR is a careful and meticulous evaluation of the relationship between hepatic lesions of hepatic veins and the glissonian pedicles. This evaluation allows the planning of the ideal anatomical roadmap for a proper resection, preserving an adequate blood inflow and outflow from the spared parenchyma. CT scanning and MRI are usually employed preoperatively for this purpose and give the possibility for different image reconstruction techniques, including 3D imaging [74, 75]. Although displaying a suboptimal sensitivity for smaller (<1 cm) lesions, triphasic CT scanning allows us to obtain an optimal

vascular and lesion assessment. Moreover, it allows for concomitant volumetric assessment of the remnant liver [76].

MRI, with the use of liver-specific contrast agents, offers a good sensitivity for smaller hepatic nodules also. Moreover, it provides a good visualization of the biliary tree anatomy, useful for planning an ideal resection plane. Intraoperative imaging through ultrasound (IOUS) is essential in PSR, since it allows the localization of even small or deep-located nodules and “navigation” into the liver following the planned resection plane precisely, visualizing and preserving vascular and biliary structures [77]. IOUS allows for a complete investigation of the vascular anatomy of the liver: hepatic veins and accessory hepatic veins can be visualized, as well as the presence of communicating vessels within adjacent hepatic veins. These communicating vessels allow us to perform a PSR even in the presence of a neoplastic involvement of a hepatic vein at a hepatic-caval confluence. They preserve an adequate venous outflow from the spared parenchyma. A successful PSR, especially in complex cases, requires excellent expertise in using this technique, as well as high quality equipment.

3.3.2. Surgical Techniques

The definition of PSR encompasses different kinds of liver resection able to maximize the liver remnant volume if compared with other, more extended, techniques.

4. LONG TERM OUTCOMES AND RISK FACTORS

One of the best curative approaches for hepatocellular cancer is liver resection [78]. This procedure is the first choice of treatment when transplantation is not feasible. Hepatic resection for HCC is safe and now displays a low operative mortality due to an improvement in pre-operative management, surgical technique and postoperative care [2]. The most important concern is the high rate of postoperative recurrence of HCC. This situation affects about 50%-60% of patients during the first 3 years and 70-90% during the first 5 years after curative hepatectomy [79, 80]. During the last decades, authors have tried to understand the pathological mechanism of HCC metastasization and the best surgical approach to reduce the recurrence rate of this tumor. Some authors underline that microscopic vascular invasion and peripheral spread of the primary tumor could cause subclinical metastases and that these could be the most important factors affecting the long term prognosis of these patients [46, 81]. Based on this premise, an extensive resection should be the best treatment for HCC. On the other hand, a massive resection can be difficult to operate on a damaged liver. HCCs frequently arise in cirrhosis. The cirrhotic liver has a limited capacity for regeneration [82]. In these cases a limited resection is mandatory, since another important cause of mortality after hepatic resection is liver failure. A limited resection could improve long term survival allowing us to preserve hepatic function and leave room for other therapeutic options [83]. The most widespread methods for patients undergoing liver resection for HCC are anatomic resection (AR) and non anatomic resection (NAR) [12, 16]. There is limited evidence supporting one of these techniques over the other [7, 84]. Several studies have compared these two techniques but they do not clearly show the advantages of AR over NAR. There are studies showing that AR improves overall survival and disease free survival since it allows

for a complete removal of tumor bearing portal tributaries [83, 85–88]. Other evidence shows no advantages of AR when compared to NAR [25, 45, 89]. AR is often indicated in patients with low-degree liver damage, while NAR is usually considered the best approach when preserving liver parenchyma and function is mandatory. The best treatment must balance resectability and preservation of liver function. The conclusion of this debate is very difficult due to the heterogeneity of studies and to the absence of randomized controlled trials. Long term outcomes can be evaluated in terms of overall survival (OS), disease free survival (DFS) and local recurrence (LR). In their study, Yamamoto et al. described a 1- and 2-year OS rate of 92.1% and 85.8% for AR and NAR, respectively, and DFS rates of 78.2% and 63%. These data suggest that there is no significant difference in terms of OS and DFS between the two groups. Furthermore, a longer hospital stay and a greater blood loss was found during surgery in the AR group. A better DFS was found in some AR subgroups. For example AR was better than NAR for patients with a tumor size of 2-5 cm suggesting that there is no difference in surgical technique when tumor size is less than 2 cm [90]. This finding could be referred to a higher tendency of larger HCCs to form intrahepatic or other organ metastasis. In the HCV positive subgroup, authors found a better DFS in the AR group. This group of patients could benefit from AR since HCV patients have a higher rate of intrahepatic metastasis compared to HBV positive patients [91]. Cucchetti et al. compared AR and NAR in Child A patients. In this study, the authors stratified the population according to time to recurrence (early vs late), tumor diameter and tumor differentiation, finding no difference between NAR and AR. AR is better than NAR when tumor diameter is larger, when there is microvascular invasion, in G3-G4 degrees and in early recurrence. On the contrary, for small, G1-G2 degree tumors, AR loses its superiority. Another important finding is that there is no difference in the rate of late recurrence in the two groups.

The rationale is to approach the patients through AR when the tumor is larger, in the presence of microvascular invasion or when the tumor is poorly differentiated. NAR is recommended when liver functionally is low or when there are no unfavorable tumor features [86]. These features can be identified during preoperative workup. Some authors related tumor size to tumor differentiation and to the presence or absence of microvascular invasion. Others identified tumor size, number, and Edmondson grade as microvascular invasion predictors. These data could be useful for surgical decision making [92, 93]. Tanaka et al. compared AR to NAR in 125 patients undergoing hepatic resection for HCC. In this study, the 1-, 3- and 5-year hepatic recurrence rates were found to be 20%, 53% and 64% in AR as opposed to 21%, 52% and 76% in NAR. The 1-, 3- and 5- year OS were respectively 96%, 70% and 54% in AR and 97%, 91% and 61% in NAR. This study showed no significant difference between anatomic and non anatomic liver resection.

At a univariate and multivariate analysis, type of resection was found not to affect survival. Furthermore, AR and NAR showed no difference in number and site of recurrent locations. In this study, authors also studied patients undergoing a second liver resection for recurrence. In patients with liver cirrhosis, the tax of second resections was higher in the non-anatomic resection group. Anyway, the proportion of patients surviving after recurrence was 16% in AR as opposed to 36% in NAR. This data probably depends on a better preservation of liver parenchyma in non anatomic resection compared to anatomic resection.

In the end, looking at patients in which a recurrence with three or more nodules has occurred, no differences were found in AR groups compared to NAR groups. Moreover, no patient had a recurrence at the margins of the resection [23].

Marubashi et al. studied recurrence patterns after NAR and AR. In this study they observed substantial differences between the two groups. Liver function of patients in the NAR group was worse than in the AR group. ICG15R, Child-Pugh score, and degree of live damage were also better in AR patients. On the contrary, AR groups included patients with a larger tumor size, higher serum tumor markers and a higher tax of microvascular invasion.

Univariate and multivariate analysis have shown that the type of liver resection was not a risk factor for tumor recurrence. This study underlined that serum AST, tumor size, multiplicity, serum albumin level and estimated blood loss were independent risk factors for HCC recurrence. Authors evaluated three different aspects of HCC recurrence: area of HCC recurrence, number of recurrent tumors and location of the recurrence. Comparing HCC recurrence patterns no difference could be detected between the two different groups. Only 1.4% of patients had a local recurrence, in the other cases recurrence was the result of systemic dissemination or de novo development. This study confirmed that the type of surgical resection to HCC is not a risk factor of recurrence. It also confirmed how the selection of the surgical method should be based on the clinical status of the patient [94]. These studies underline that the type of surgical resection is not a risk factor for HCC recurrence and consequently, does not affect long term outcomes. These results suggest there are others factor that influence prognosis more than the type of surgery.

Some studies report that HCV infection, Child-Pugh class B, $AST \geq 35$ UI/L, $PLT < 14 \times 10^4$ microliter, $ICG-R15 \geq 25\%$, $AFP \geq 20$ ng/mL, cancer spread and cirrhosis affect DFS. Child-Pugh class B, $PLT < 14 \times 10^4$ microliter, $ICG-R15 \geq 25\%$, $AFP \geq 20$ ng/mL, cancer spread, cirrhosis and infiltration into the capsule seem to affect OS, instead [45]. Another study found that preoperative serum AST, prothrombin time, tumor size, albumin, multiplicity and estimated blood loss were independent risk factors for HCC recurrence. This study further demonstrated that the resection method does not affect HCC recurrence [94]. These data suggest that the clinical status influences long-term prognosis more than the kind of liver resection.

Tomimaru et al. studied retrospectively a selected population affected by HCC. Authors selected a population with a small solitary HCC (≤ 3 cm) without macroscopic vascular invasion and with an adequate underling liver function. This study showed no differences in short-term and long-term outcomes. Furthermore, univariate analysis proved that the presence of HBV, HCV, microscopic invasion and number of microscopic tumors affect DFS. HCV and microscopic vascular invasion were linked to DFS in multivariate analysis as well. On the other hand, the number of microscopic tumors, HCV and liver cirrhosis were related to OS at univariate analysis, while only the number of microscopic tumors was connected to OS at multivariate analysis [95]. These results underline the importance of the patients' clinical background and of tumor features. The presence of a chronic inflammation of the liver, cirrhosis, the presence of microvascular inflammation or multiple nodules are risk factors for recurrence and affect short-term and long-term outcomes.

Eguchi et al. compared AR and NAR in a cohort of 5781 patients with a single HCC. Stratifying patients for tumor size, they found that HCCs ranging from 2 cm to 5 cm benefit from AR rather than NAR. Furthermore, in HCCs smaller than 2 cm, no difference was found in long-term survival. Authors also stratified patients for liver function. In this respect, differences between AR and NAR disappeared, also, for tumors larger than 2 cm [84]. Our group tried to compare long term outcomes of NAR and AR. In this study we used a propensity score analysis to reduce biases. We analyzed retrospectively 455 patients. We

found an OS of 47.6 months for AR and 56.5 months for NAR ($p=0.169$). The median DFS was 29.2 months for AR and 24.9 months for NAR ($p=0.337$). At univariate analysis, we found that the presence of cirrhosis, BCLC stage, microvascular invasion, satellitosis, surgical resection margins, postoperative liver failure, postoperative ascites, number of nodules, size of nodules and ALBI grade were associated with a reduction in OS. Using a multivariate regression model, we found that cirrhosis, microvascular invasion, BCLC grade B, presence of satellitosis, postoperative ascites, grade 3-4 Clavien-Dindo classification and ALBI grade 2 were independently associated with OS. Furthermore, cirrhosis, BCLC grade, microvascular invasion, presence of satellitosis, postoperative ascites and number of nodules were all associated with early recurrence (DFS < 2 years). At the multivariate Cox regression model: presence of cirrhosis, grade B BCLC, microvascular invasion and satellitosis were independently associated with the risk of recurrence.

Our study demonstrated no differences between AR and NAR as well. Furthermore, we also appreciated the importance of liver function and tumor characteristics as the most important factors affecting OS and DFS. In the end, studies suggested that the type of surgery is not an independent risk factor for HCC recurrence. Tumor-related factors appear to be more relevant than type of surgery in affecting the risk of HCC recurrence.

5. RECURRENCE PATTERN AFTER RESECTION: INTRA-HEPATIC METASTASIS OR DE-NOVO RECURRENCE

Pattern of recurrence is a main topic in HCC therapeutic strategies. The peculiarity of this tumor is the background parenchyma in which it develops. In the majority of cases it is characterized by a chronic inflammatory state rather than by outright cirrhosis. In fact, when a new nodule is diagnosed, or when the tumor arises as a multinodular disease, no clinical or biochemical features are able to distinguish between the occurrence of a de-novo nodule (multicentric occurrence, MO), favoured by the chronic underlying inflammatory state of the liver, and the real intrahepatic metastasization (IM) of a primitive lesion. The ability to distinguish between these two occurrences would affect our interpretation of the phenomenon and change the current figures on hepatocarcinoma recurrence.

These considerations become fundamental when we consider that multinodular disease currently has no indication to curative treatment although it could possibly be the expression of de-novo multicentric carcinogenesis rather than of intrahepatic metastasization. The effect of cirrhosis on recurrence has been recently investigated by Sasaki et al. [96], who compared cirrhotic and healthy patients. Their results showed how cirrhosis can affect the pattern of recurrence, increasing the chances of MO [19] over IM.

However, they reported a comparable rate of early recurrence, which they interpreted as the expression of the metastatic potential intrinsic in hepatocellular carcinoma. Thus, a cirrhotic liver, when compared to a healthy one, seems to be characterized by the possibility of metastasization, as well as by the occurrence of de-novo neoplasm through the chronic inflammatory boost of the underlying cirrhosis. In the last decade, experimental genetic analysis has allowed us to improve our knowledge of recurrence patterns in HCC. Studies on Asian databases described an IM rate of between 50-70% after liver surgery [97-99]. The same authors reported how the IM pattern seems to have a worse prognosis compared to

tumors that recur with a MO pattern [98–100]. A recent meta-analysis has confirmed this trend on seven reports [100], all of them on Asiatic data. To the best of our knowledge, no western data is available in literature regarding the incidence of the two patterns. Many efforts have been made to understand the different conditions that lead to IM rather than MO. Most studies point out the main role of the MVI as “primum-movers” in the metastasization pathway [101–103].

The role of microvascular invasion in recurrence was first explored by Makuuchi et al. in 1985 [48]. The authors reported a rate of 73% of 62 HCC patients showing a microscopic tumor thrombus in the portal venous branch. From this manuscript came the proposal of a resection technique able to cut off the tumour portal supply according to Coinaud segmentation. This approach should allow the reduction of the rate of recurrence. Up to now, there is still no accord among the multiple experiences all over the world concerning the real impact of this approach on recurrence. According to a recent systematic review, the rate of microscopic portal vein thrombosis in the tumor area is definitely smaller than expected, varying according to different tumor sizes: 0.5% for early cancer, 16.2% for tumors of less than 2 cm, 17.4% when size is <5cm, as high as 64% for tumors larger than 5 cm [104]. Furthermore, the theory of cancer spread through portal circulation is not able to explain the rate of recurrence after transplantation, a very rare but possible occurrence.

Over the last few years, especially through the Osaka Hospital (Japan) experience, new data has emerged that could clarify the mechanism of intrahepatic metastasization. CT studies during arterial portography and hepatic arteriography allowed Sakon et al. to define three different patterns of intrahepatic recurrence. 1) Local IM: HCC recurrence around the tumor, caused by direct spread through the portal blood flow or venous drainage; 2) Systemic IM: HCC recurrence caused by circulating tumor cells; 3) MC: multicentric HCC recurrence caused by de-novo development of hepatocarcinoma [17–19, 104]. These authors also evidenced the role of tumor blood flow (TBF) drainage, which appears at CT scan as the vascular supply area of the tumor, which is not always directly related to the segmental portal branch distribution around the nodule. They stated how the different patterns of recurrence are significantly associated with different TBF drainage patterns.

Local diffusion is the manifestation of anatomical dissemination (depicted by the portal vein type at TBF drainage) rather than non-anatomical (represented by the marginal or hypovascular TBF type). More recently, Marubashi et al. underlined the importance of overcoming the old theory of portal vein dissemination as the main route for intrahepatic metastasization, favoring the tumor blood flow drainage theory over the systemic rehomings theory [6].

Given the different types of recurrence that can occur in the context of hepatocarcinoma, there are still few reports about the real impact of surgery on reducing recurrence rate. As already discussed, most physicians assume that, when metastasization is due to MVI, a radical excision of the anatomical liver segment with its portal vascularization, should achieve the best outcome in terms of recurrence [10, 105, 106]. However, many authors have reported no differences between AR and PSR in long term-oncological outcomes [107, 108]. A recent, combined Asian and Western-based study [109] showed no differences in long-term outcomes between the two surgical techniques. AR seems to reduce the rate of early recurrence in cancers with MVI or with a G3-4 differentiation pattern according to Edmonson’s histological classification. Early recurrence has been defined as a possible clinical indicator of the metastasization pattern in HCC [100, 101, 109]. Marubashi et al. [6]

compared the two surgical techniques and their respective patterns of recurrence. No significant differences were evident in the local dissemination rate after surgery, neither when comparing intrahepatic and extrahepatic recurrences, nor on the localization of the recurrent nodules. These results reflect the difficulty in estimating the real impact of different recurrence patterns on long terms outcomes.

Lesions characterized by a different tumor burden can express different carcinogenic potentials. This power is independent of the surgical technique. In fact, according to the “re-homing theory” [17, 18], used to explain recurrence after transplantation, once the hepatocellular nodule acquires the features of invasiveness, metastasization can equally occur in the liver and in the blood flow, so that neither of the currently available therapies can possibly reduce or cancel the risk of recurrence.

Others studies, analyzing recurrence patterns after surgical resection, presented similar results. Local dissemination after PSR apparently concerns just a minority of cases, most HCC recurrences being apparently caused by systemic dissemination of circulating tumor cells or multicentric occurrence of de-novo HCC [6, 22]. According to these considerations, it may be easy to understand the importance of finding a procedure able to distinguish between IM and MO.

Different efforts have been made to distinguish the two patterns by genetic analyses. CGH-arrays, microsatellite instability, loss of heterozygosity and other genetic features have been diffusely employed to characterize the differences between a primitive nodule and its recurrence. More recently, variations of the mitochondrial DNA of hepatocellular carcinoma were explored, with interesting results and good sensitivity and specificity [110]. These procedures, however, are affected by the impossibility of predicting a recurrence pattern during the preoperative work-up.

Genetic analysis can only be performed on histological specimens, so that the real nature of the treated lesion can only be recognized a-posteriori. Shimada et al. [111] reported C hepatitis infection, a platelet count of $<10 \times 10^4/\mu\text{mol}$; tumor size and histological grade as independent factors in differentiating MO from IM. Nakano et al. [111, 112] reported that a tumor capsule was rarely observed in IM patients. Different authors stated that large and multinodular HCC have always presented a high incidence of recurrence, and that these types of multinodular HCCs were more usually identified as IM [113, 114]. More recently, a recurrence-free interval of over 18 months after initial hepatic resection has been suggested as a cut-off point to differentiate MO from IM in clinical practice [115]. Other authors have pointed out a cut-off of 2 years for RFS [116].

However, some retrospective series do not support this clinical approach, recording no difference in outcomes when time to recurrence is employed to distinguish between different recurrent patterns and to predict different outcomes of AR and PSR. Until now, no reliable and universally accepted clinical models are available to predict the pattern of recurrence of HCC. To conclude, PSR seems comparable to AR as a treatment for hepatic cancer. Where recurrence is concerned, distant intrahepatic recurrence is more common than surgical hedge relapse or distant metastases. This evidence further points towards the need for a reinterpretation of the mechanism underlying recurrence in hepatocarcinoma, revisiting the portal-flow-theory and our general approach to the disease.

6. EXTENDING THE ROLE OF SURGERY: FROM BENCHMARK TO BEDSIDE

To better address these clinical questions, molecular characterization has been performed on multiple liver tumor specimens through various analyses, using new biological mechanisms and molecular markers. In recent years, a better knowledge of mutational and epigenetic events deregulating the signaling pathways involved in tumor progression, and the definition of different genetic variants of HCC, have allowed a better of recurrence patterns, the prediction of disease outcomes and the identification of potential prognostic markers and targets for molecular-based personalized therapies [117, 118]. Some studies used the HBV-DNA integration pattern, the X chromosome inactivation assay, and comparative genomic hybridization (CGH) as possible markers of tumor clone origin [119, 120]. However, all of these methods have inherent limitations. They can be applied only to HCC patients with integrated HBV-DNA, only to female patients or require expensive equipment and reagents, respectively.

Moreover, HBV integration testing through southern blotting requires a consistent amount of DNA genome [121]. Micro-satellite polymorphism, including loss of heterozygosity (LOH) and microsatellite instability (MSI) are important genetic features in carcinogenesis. LOH analysis of specific DNA microsatellite loci were performed in the attempt to distinguish IM of monoclonal origin, from multiclonal MO [98, 122]. Compared to other molecular methods, the test of microsatellite polymorphism with Polymerase Chain Reaction (PCR) and Polyacrylamide Gel Electrophoresis (PAGE) shows many advantages. Moreover, it can be used on small quantities of DNA genome that can be acquired from tiny specimens such as fine-needle biopsy specimens. DNA microarray technology is currently employed in identifying specific gene expression signatures of HCC. Recently, this technique has been used to predict early HCC recurrence due to intrahepatic metastasis; however, no well-defined predictors for late recurrence have been discovered. Some studies have focused on the characteristics of non-tumorous liver to predict late recurrence due to de novo hepatocarcinogenesis. These studies were based on the idea of “field cancerization” but did not lead to conclusive results [123]. In another study [124], the gene expression signature of primary metastatic HCCs was found to be similar to that of the corresponding IMs, implying that the genetic deregulation responsible for metastasization initiates within the primary tumor. The Adrenomedullin (AM) gene was identified as a leader gene overexpressed in HCCs with IM, while a different gene expression profile was observed in multicentric HCCs [124].

Several studies based on large-scale genome sequencing have been performed to identify the driver genes in carcinogenesis [125–128]. The objective was to detect the most frequently mutated genes among many different singular cases. However, identifying the driver genes in the long list of less frequent mutation proved difficult. One important new trend for delineating HCC biomarkers is the proteomic approach. It allows us to identify variations in levels of protein expression in liver tissue or plasma during the progression from liver fibrosis, cirrhosis or steatohepatitis to HCC [129]. The same approach was used with reference to molecular diagnosis and metastatic recurrence of HCC [130]. However, research focusing on the study of the pathogenesis of IM and MO by proteomic approach is at its beginning; studies are few and performed on a limited number of patients. Therefore, it is not

currently possible to estimate whether the newly identified proteins are effectively potential biomarkers for identifying the multinodular HCCs of clonal origin and for discriminating between IM and MO cases.

Many efforts have also been dedicated to the exploration of new biologic mechanisms and molecular markers of multifocal HCC through omic analysis. The omic strategy includes the research of diagnostic and progression markers through genomic, proteomic and metabolomic analyses in order to evaluate gene, protein and metabolic deregulations. In this field, an undoubtedly innovative research has been recently published by Miao et al. [131], who performed a multi-omic analysis to differentiate MO from IM by decoding molecular differences between the two multifocal HCC models. This would allow us to identify molecular markers for diagnosis and prognosis, as well as therapeutic targets. They analyzed intrahepatic HCC lesions and matched non-cancerous liver tissue and blood obtained from representative patients with HBV-related multifocal HCC undergoing tumor resection and marked by distinct post-surgical courses. The samples were subjected to multi-omic analyses, integrating genomics and transcriptomics; the results, further validated by a cohort of 174 HCC patients, were correlated with clinicopathological data.

The determination of HBV integration in the different lesions clearly suggested the existence of different tumor clonality. The evaluation of genomic alterations showed how the enrichment of pathways including cell cycle, p53 signaling, histidine metabolism, G2/M checkpoint, and Ran (Ras-related nuclear protein)-mediated mitotic spindle regulation was associated with clonal metastasization rather than with the synchronous development of distinct clones. Protein analysis showed a significant difference in the synchronous development of multicentric primary HCC and metastatic disease. Validation analysis confirmed the upregulation of six out of seven genes: Histidine ammonia-lyase (HAL), stratifin 14-3-3 γ (SFN), kinesin superfamily protein 15 (KIF15), dual-specificity protein kinase (TTK), Budding uninhibited by benzimidazoles 1 homolog (BUB1) and minichromosome maintenance complex component 4 (MCM4).

Different clinicopathologic features of HCCs were significantly associated with at least one of these genes. In addition, the evaluation of the relationships between the expression of the above genes and metastatic potential and postsurgical recurrence strongly suggested that TTK expression could be an independent prognostic indicator for HCC patients. In addition it could differentiate MO from IM. Multi-omic profiling could provide essential information for evaluating the aggressiveness of the existing lesion and for applying personalized therapies, including post-surgical treatments. It must be considered that cases of IM, with several nodules exhibiting different molecular alterations, require multi-omic analysis of each new nodule in order to identify critical molecular lesions which could be the targets of specific treatments.

Although the multi-omic strategy potentially opens new groundbreaking perspectives for diagnosis, prognosis and treatment of multifocal HCC, it still presents important limitations. The analysis should be extended to wider and more heterogeneous cohorts. Moreover, its clinical application could be seriously limited by the complexity of the analysis and by the elevated costs. Nonetheless, the innovative results of the multi-omic approach promotes new efforts to overcome these drawbacks.

LAPAROSCOPIC LIVER RESECTION FOR HEPATOCELLULAR CARCINOMA PATIENTS: INDICATIONS AND BENEFITS

Zenichi Morise*, MD, PhD

Department of Surgery, Fujita Health University School of Medicine
Toyoake, Japan

ABSTRACT

The treatment options for hepatocellular carcinoma (HCC) include liver resection (LR), liver transplantation (LT), transarterial chemoembolization, and local ablation therapy. LR and LT, and local ablation therapy (for small tumors only) provide the best hope for cure. However, most patients with HCC have underlying chronic liver disease (CLD) and are thus at high risk for development of postoperative complications - sometimes fatal- and metachronous multicentric recurrent lesions occurring from the preneoplastic CLD background. Although appropriate treatment is selected for HCC patients with CLD depending on the tumor condition and liver function, a large number of patients are not able to undergo any treatment because of poor liver function and/or complicated tumor condition. This is especially true after repeated treatments for the disease.

In our experience of laparoscopic LR (LLR), LLR could expand the indication of LR to severe CLD patients due to its lower damages to the liver and surrounding tissue, especially to collateral circulation around the cirrhotic liver. Child-Pugh score, not class, is one of the promising candidates as a selection indicator which correlates well to our indication criteria of surface small LLR to severe CLD patients, patient's performance status, and prognosis. Portal hypertension should also be counted in the selection criteria.

For repeat LLR, there are only small number of reports with small number of patients to date. These studies generally reported that repeat LLR has better short-term outcomes than open (reduced bleedings, less or similar morbidity and shorter hospital stay) without compromising the long-term outcomes. The fact that complete adhesiolysis can be avoided in repeat LLR is also reported. In the comparison of previous procedures,

* Corresponding Author's Email: zmorise@fujita-hu.ac.jp.

it is reported that the operation time for repeat LLR was shorter for the patients previously treated with LLR than open. Furthermore, it is speculated that LLR for minor repeat LR of cirrhotic liver can be minimized the deterioration of liver function by LR. However, further experience and evaluation of anatomical resection or resections exposing major vessels as repeat LLR, especially after previous anatomical resection, are needed.

It is thought that the features of LLR could lead to expanding the indications for LR to those patients in the settings of severe CLD, repeat LR, and bridging to LT. There should be a chance to prolong the overall survival of the patients by using LLR as a powerful local therapy which can be applied repeatedly with minimal deterioration of liver function.

INTRODUCTION

General Situation of the Treatments for Hepatocellular Carcinoma (HCC) Patients with Chronic Liver Disease (CLD)

The treatment options for HCC include liver resection (LR) [1], liver transplantation (LT) [2], transarterial chemoembolization, and local ablation therapy [3]. LR, LT and local ablation therapy (only for small tumors) provide the best hope for cure [3-6]. However, most patients with HCC have underlying chronic liver disease (CLD) and are thus at high risk for development of postoperative complications and metachronous multicentric recurrent lesions occurring from the preneoplastic CLD background.

Currently, the choice of LR, LT, local ablation therapy or transarterial chemoembolization is made for each patient depending on the tumor condition and liver function [7]. However, a large number of HCC patients are not able to undergo any such treatment because of poor liver function and/or complicated tumor condition. This is especially true after repeated treatments for the recurrent disease.

Among the treatment options mentioned above, LT should be ideal for HCC patients with CLD in the aspect of removing both existing tumors and injured/preneoplastic underlying liver. However, it cannot be applied on a large scale due to the high prevalence of HCC and the limited access to LT consequent to donor shortage [8]. LT is also restricted to patients with minimal risk of tumor recurrence under immunosuppression [9]. Expansion of the criteria for LT in HCC patients is still under trial and discussion [10, 11]. Therefore, LR has traditionally been accepted as the preferred treatment for resectable HCC in patients with adequate liver reserve [6, 12, 13].

When considering LR to HCC patients with CLD, not only the oncological therapeutic effects, but also the residual liver function and the degree of invasive surgical stress, especially to the diseased liver should be considered. Patients with CLD have various symptoms [14] and a high risk of morbidity and mortality following anesthesia and surgery depending on their Child-Pugh (CP) class [15, 16]. For severe CLD patients, even limited LR often leads to refractory ascites, which can be a fatal complication [17, 18].

Considerable progress made over the past 10 years in screening, early radiologic diagnosis, treatment of the underlying CLD, and surgical techniques has resulted in revision of the indications for LR [19]. Furthermore, improved liver function assessment and understanding of segmental liver anatomy from using more accurate imaging studies, as well

as surgical technical progress, are the most important factors that have reduced the mortality rate of HCC; today, the expected 5-year survival after LR is 38%-61%, depending on the stage of the disease [20]. Despite these advances, however, less than 30% of HCC patients are eligible for LR [21, 22].

Emerging evidence from laparoscopic (L)LR [23, 24] may lead to expansion of the indication for LR in the therapeutic system for HCC patients with CLD. In this article, the current reports on LLR for HCC patients with CLD are reviewed and our experiences are described.

LLR for HCC Patients with CLD

The beginnings of LLR were at the start of the 1990s, with its initial reports [25-27] being published in 1991 and 1992. Thereafter, the indication of LLR has been expanded as a less invasive procedure than conventional open (O)LR for hepatic lesions. LLR has the benefit of earlier intake, recovery and discharge, and reduced postoperative pain, like other laparoscopic procedures [28]. A meta-analysis of 26 studies found that, although LLR was associated with longer operating times, the oncologic outcomes were not different from OLR [29]. Furthermore, studies showed the specific advantages associated with LLR, such as reduced blood loss, decreased portal clamp time, and decreases in overall and liver-specific complications at least for selected patients and within the technical capabilities of each experienced center.

The safety and feasibility of LLR and its short-term benefits for HCC patients with CLD have also been demonstrated [30-32]. LLR may be particularly advantageous for HCC patients with CLD, who often develop refractory ascites with OLR, a potentially fatal complication [17, 18]. LLR has the advantage of minimal ascites, due to the preservation of venous and lymphatic collateral circulation [35], which lowers the risk of water/electrolyte imbalance and hypoproteinemia that could trigger fatal liver failure. This feature could be the most remarkable advantage of LLR.

Patients who undergo LR are exposed to three different types of stresses: 1) general, whole-body surgical stress; 2) reduced liver function due to reduced liver volume after resection; and, (3) surgery-induced injury to the environment surrounding the liver and liver parenchyma (caused by disruption of the collateral blood and lymphatic circulation with laparotomy and mobilization of the liver, and parenchymal injury by compression of the liver) [33]. LR is the procedure that the liver protected inside the subphrenic rib cage is resected. In OLR, the cage is opened with a big subcostal incision and a lift of the costal arch, and then the liver is picked up for resection with the dissection of retroperitoneal attachments. On the other, in LLR, laparoscope and forceps intrude into the cage directly from the caudal direction ("Caudal approach" [34-36], Figure 1) and perform LR in the small targeted area without damages to the surrounding area. Furthermore, the same surgical view under position changes, acquired by the adjustments of laparoscope's positioning and rotation in LLR, allows for handling large-volume liver/tumor by postural changes. This leads to the reduction of compression damage on the liver. Our previous report of the caudal approach posterior sectionectomy in the left lateral position [34] posed the novel concept of "caudal approach" in LLR. Although the supine to semi-lateral positioning had been employed for the other resections, the transection plane of posterior sectionectomy was horizontal in the supine

position and gravity obstructs the exposure of the plane. A clear view from the caudal direction and an easy access to postural changes are among the advantages of LLR (Figure 1). Our procedure is a laparoscopic posterior sectionectomy with parenchymal transection prior to mobilization in the left lateral position. It facilitates exposure of the cutting plane during the transection in caudal-to-cranial one direction. The transection plane is well-opened between the retroperitoneal-fixed posterior section and the remnant liver falling down to left by gravity. Moreover, the segmentectomy or partial resection of segment (S)7 should be performed in the deeper and smaller cranial subphrenic space and S6 is an obstacle under the laparoscopic caudal view even in the left lateral position. We employed the semi-prone position with only partial dissection of the retroperitoneum for those resections [37]. LLR can facilitate minimal dissection around the liver and minimal compression on the liver with the intrusion and manipulation of laparoscope and forceps to the small target area ("Caudal approach" Figure 1) under postural changes. Therefore, LLR's reduction of surgery-induced injuries in HCC patients with CLD lowers the risk of refractory ascites, resulting in a reduced risk of successive complications and facilitating a smoother recovery without liver failure.

The impact of LLR on this issue should depend on the severity of the background CLD, the operative technique (extent of dissection of the peritoneal attachments and adhesions), and extent of resection. Our previous study compared the short-term results of liver surface small LLR for patients with severe CLD (CP-B/C and indocyanine green retention rate at 15 min (ICGR15) $\geq 40\%$) to those for patients with mild-moderate CLD [38]. Although the study was a small number, retrospective unmatched study, it revealed comparable perioperative outcomes, including postoperative ascites production, between patients with severe and mild-to-moderate CLD in LLR.

Figure 1. Schema of laparoscopic liver resection (LLR, A), and position changes in LLR (B). Red arrows indicate the directions of the view and manipulation. In the open approach, the subcostal cage containing the liver is opened with a large subcostal incision, and instruments are used to lift the costal arch up (A, cross mark). The liver is dissected and mobilized (picked up) from the retroperitoneum (A, cross mark). A: In the laparoscopic caudal approach, the laparoscope and forceps intrude into the subcostal cage from caudal direction, and surgery is performed with minimal alteration and destruction of the surrounding structures. B: In the laparoscopic approach, the same surgical view under position changes (tilting the bed and rotation of the patient's body), acquired by the adjustments of laparoscope's positioning and rotation, allows for handling large-volume liver/tumor by postural changes.

Repeat LLR

As mentioned above, HCC arises in metachronous multicentric fashion inside the liver with its preneoplastic CLD backgrounds. Intrahepatic recurrences after previous resection of HCC with the need for repeat treatments often occur.

LR is now actively applied to those lesions, when the lesions are resectable and there is no other uncontrollable/distant disease, and the opportunity for repeat LR has increased [39-42]. Currently, indications of LLR have been expanded with the accumulation of experiences and technical/conceptual and instrumental developments [24, 43-45]. Postoperative adhesions with the need for adhesiolysis are known to increase the operation time of subsequent surgeries and the incidence of bowel injury [46, 47]. Therefore, increased rates of complications and conversion from laparoscopic to open surgery had been reported in repeat laparoscopic surgery [48]. Although a previous surgical history had been among the contraindications for laparoscopic surgery, many laparoscopic procedures, such as cholecystectomy [47, 48], appendectomy [49], colectomy [50], and gastrectomy [51], can be applied to those patients nowadays with technical and instrumental improvements. However, since LLR still remains a technically demanding procedure, the indications and efficacy of repeat LLR are under discussion. Adequate dissection of adhesion and mobilization of the involved liver should be performed before repeat LR. Visualization and dissection of the hepatoduodenal ligament and hilar area, often crucial in LR, can be disrupted by adhesion. The deformity of the liver surrounded by the scars and adhesion makes the localization of tumors and the important structures (vessels) difficult. The fact that liver capsule bleeds easily during adhesiolysis and mobilization leads to increase the intraoperative bleeding and create a suboptimal operative field [52]. These changes after previous surgery can increase the risks of intraoperative injury to vascular and biliary structures.

Although the reports of repeat LLR are gradually increasing, only 16 reports of small series were found out under Medline-search with the words “repeat” and “laparoscopic liver resection” and their re-quotations [53-68]. Belli et al. [55] reported that LLR facilitates more meticulous dissection of adhesions strained by the pneumoperitoneum using magnified laparoscopic view. The fact that complete adhesiolysis can be avoided when the adhesion does not affect the current operative procedure (which is on the same line of LLR characteristics mentioned in the previous section “LLR for HCC patients with CLD”) is also reported as a possible advantage of repeat LLR [59, 64]. In comparison with repeat OLR, these studies generally reported that repeat LLR has better short-term outcomes (similar or longer operation time, reduced bleedings, reduced blood transfusion rate, less or similar morbidity and shorter hospital stay) without compromising the long-term outcomes. Each report concluded that repeat LLR is feasible and safe for selected patients. However, those studies are the mixtures of the patients with HCC and metastases. Five studies of repeat LLR, which only include HCC patients [55, 59, 61, 62, 66], reported the outcomes for the series of 12, 6, 3, 20 and 8 patients. The conclusions of all studies are that repeat LLR is a safe and feasible procedure even for recurrent HCC in CLD patients. Belli et al. [55] again mentioned that the adhesiolysis was easier and the operation time was shorter in repeat LLR for the patients with previous LLR compared to previous OLR. They also referred the advantages of LLR for the management during the long history with repeat oncogenesis in CLD patients. Kanazawa et al. [62] mentioned that the complication rate and the hospital stay had been decreased in their institute by the introduction of LLR for recurrent HCC patients. Repeat

LLR requires smaller (than open) working space between adhesions where laparoscope and forceps can intrude and do manipulation. This fact allows for minimal adhesiolysis and a direct approach to the tumor especially in repeat small LLR [58, 59, 64]. Therefore, some studies showed that operation time and bleeding amount were similar in primary and repeat LLR [53, 64], although the short-term results from primary and repeat OLR are usually very different especially in operative time (longer in repeat) and intraoperative blood loss (larger in repeat). Operation time and bleeding amount could be reduced with the usage of laparoscopic approach for repeat partial resection. Furthermore, one of the possible advantages speculated for minor repeat LLR of CLD liver is that the deterioration of liver function can be minimized with the minimal dissection (Table 1).

Table 1. The summary of present status of repeat LLR

- Operation time was shorter and the adhesiolysis was easier for the patients previously treated with LLR than open LR.
- LLR facilitates more meticulous dissection of adhesions strained by the pneumoperitoneum using magnified laparoscopic view.
- Complete adhesiolysis can be avoided in repeat LLR when the adhesion does not affect the current operative procedure, since it requires smaller (than open) working space between adhesions. (This allows that operation time and bleeding amount are similar to primary LLR, although those from open LR are longer and larger.)

LLR could prolong the overall survival of the HCC patients with CLD as a powerful local therapy which can be applied repeatedly with minimal deterioration of liver function.

Challenges:

Further evaluations of anatomical resection or resections exposing major vessels after previous anatomical resection are needed.

LLR Indications to Severe CLD Patients

For the treatment selection of HCC, the Barcelona clinic liver cancer (BCLC) staging system/treatment algorithm [69] and the Japan Society of Hepatology clinical guidelines for HCC (JSH guideline) [70] are used in Western countries and Japan, respectively. Both systems include not only tumor condition but also background liver condition for the treatment selection. The two differ in that the BCLC algorithm uses CP classification (CP) [71] for assessments of liver function, while the JSH guideline uses the liver damage (LD) classification of the Liver Cancer Study Group of Japan [72], which has ICGR15 as one of the essential elements.

ICGR15 is a useful modality for assessing hepatic functional reserve and predicting postoperative mortality [73-75]. The extent of the liver resected in each patient is basically planned according to the tumor condition and location. However, HCC patients sometimes develop postoperative liver failure due to poor liver functional reserve after the planned resection. ICGR15 has been an excellent tool for predicting how much liver volume could be resected in each patient's liver condition [74]. On the other hand, nontumorous functioning

liver parenchyma is resected minimally in liver surface tumorectomy or small partial resection. In those cases, the most important point for preoperative evaluation is, not how much liver volume could be resected, but whether the patient and the liver could tolerate the surgical stress. As mentioned before, LLR minimizes the surgery-induced injury caused by disruption of the collateral blood and lymphatic circulation and compression on the liver parenchyma, and leads to decreased postoperative ascites and liver failure [33]. The decision-making process during liver surface small partial LLR should be different from the other liver resections.

Our Experiences of LLR for HCC Patients with CLD

Among 152 patients, 19 had more than 30% ICGR15 and HCC. The details of these patients are presented in Table 2. The 19 patients were composed of 6, 11 and 2 patients with CP-A, B and C, respectively. By LD classification, they included 2, 12 and 5 patients of LD-A, B and C, respectively. There was discrepancy between the liver functional assessments of CP and LD. The patients with high ICGR15 values tended to be classified into higher grade of liver dysfunction in the LD classification. Based on liver functional criteria only of BCLC and JHS, there were already 2 and 5 patients out of LR indication in this group, respectively. We applied liver surface small LLR to the CP-B/C (up to CP score of 10) patients only when the patients could have been doing light or household labor for more than 6 months before their surgery, in a stable condition (good performance status).

Excluding the 1 patient whose follow-up period is less than 24 mo and the 1 patient who underwent LT at 15 months after LLR, 7 patients died of HCC or liver disease within 24 months after LLR (D group). When the D patients were compared to the group of 10 patients who survived more than 24 months (A group), there are significant difference in CP scores between the groups (Table 3). The values of ICGR15 are similar in the A and D groups. All of the D patients, but only 3 of the 11 A patients, had esophageal varices before surgery. All of the A patients, excluding the patients with LT at 15 months, had 50,000 or more blood platelet counts, and 5 out of 7 D patients had below 60,000.

It is thought that ICGR15 above 30%-40% is out of their reliable range and not well-correlated with actual liver function. Thus, it may not be suitable for the liver functional selection criteria of surface small LLR, even though it is very useful and simple criteria for judging how much liver volume can be resected in the range below 30%-40%. Although the difficult judgements for the objective presences of ascites and encephalopathy should be needed, CP score is a promising candidate for selection indicator of surface small LLR, correlating well to our indication criteria, patient's performance status, and prognosis after the surgery. Portal hypertension [76], indicated by the presence of esophageal varices and low platelet counts, should be also counted in the selection of surface small LLR.

Table 2. Our cases of laparoscopic liver resection (LLR) for severe chronic liver diseases (CLD)

Age	Sex	Tumor location	Tumor size (mm)	Conversion	Previous surgery	LT after LLR	ICGRI5 (%)	CP	Platelet (X10 ⁹ /μl)	Prognosis (month)

*1 patient who underwent liver transplantation at 15 months after LR was excluded from group A; **1 patient after splenectomy was excluded from group D; # statistically different. CP: Child-Pugh classification score; HCC: Hepatocellular carcinoma; ICGR15: Indocyanine green retention rate at 15 min.

Most reported cases of repeat LLR underwent minor resection for HCC patients with CLD, as mentioned above. The impact of alterations to hepatic parenchyma and intrahepatic structural anatomy from the previous LR could be relatively small in such cases. However, in our experience of 33 repeat and 12 three or more-time repeat LLRs, three patients who underwent anatomical resection or resections exposing major vessels (including S8 segmentectomy after 4-times LLR [77]) after previous anatomical resection developed postoperative bile leakage and more than 30 days postoperative hospital stay. Since anatomical alterations and surrounding scars and/or adhesion of hilar and intrahepatic vessel structures should have big impacts on anatomical resection or resections exposing major vessels as repeat LLR after previous anatomical resection, further experiences and evaluations of such repeat LLR are needed.

CONCLUSION

The characteristics mentioned above indicate that LLR may be superior to OLR under certain conditions. The LLR could also be an optional bridging therapy to LT for certain HCC patients with severe CLD [31]. The recent development of LLR and accumulation of experience could lead to an expansion of the indication for LLR [45]. Although the number of studies reported has been small and comprising various settings, we believe that the features of LLR that have come to light will lead to expanding the indications for LR to HCC patients with background CLD, particularly in the settings of severe CLD, repeat LR and bridging to LT.

POST-CRANIOTOMY TEMPOROMANDIBULAR DYSFUNCTION: PATHOPHYSIOLOGY, DIAGNOSIS AND TREATMENT

***Thiago Martinelli, Fernando Akio Maeda,
Claudio Frões de Freitas and Andre Luiz Ferreira Costa****

Department of Orthodontics and Radiology, University of City of São Paulo (UNICID),
São Paulo, SP, Brazil

ABSTRACT

Several surgical procedures can be used to perform craniotomy, such as the classical pterional, pre-temporal and other fronto-temporal approaches. However, they are all based on the dissection of the temporal muscle, which can lead to temporal muscle atrophy, pain in the temporomandibular joint or masticatory muscles, weakness of the jaw closure, and development of signs and symptoms of temporomandibular joint dysfunction, all significantly compromising the patient's quality of life. This type of temporomandibular dysfunction has been frequently neglected as only good results of the primary disease are considered. The following review presents a synopsis of the pathophysiology of post-craniotomy temporomandibular dysfunction and a practical approach to its evaluation and treatment.

Keywords: temporal muscle atrophy, risk factors, facial pain, temporomandibular joint, myofascial pain

INTRODUCTION

Orofacial pain can arise from a variety of disorders, including atypical idiopathic facial pain, temporomandibular dysfunction (TMD), dental pain, soft tissue diseases, neuralgia and

* Corresponding Author's Email: alfcosta@gmail.com.

headaches (Romero-Reyes & Uyanik, 2014). TMD is considered the main cause of pain in the orofacial region from odontogenic origin (Ahmad & Schiffman, 2016).

The aetiology of TMD is considered multifactorial, being comprehended in a biopsychosocial context (Manfredini, 2010; Marklund & Wanman, 2010). Although the prevalence of TMD changes depends on their pathology, it is reported that 75% of the general population have asymptomatic TMD (Costa, D'Abreu & Cendes, 2008).

The three cardinal features of TMD are orofacial pain, joint noise and restricted jaw function. Pain is the most common complaint and the primary cause for patients asking for help and treatment, thus being the principal goal of diagnosis and treatment (Manfredini, 2010).

As TMD is a musculoskeletal disorder affecting the temporo-mandibular joint (TMJ) and masticatory muscles, the pain exacerbated by the mandibular function is a pathognomonic sign of TMD (Kapur, Kamel & Herlich, 2003). It has been reported that nearly 50% of all TMDs are masticatory myalgias or masticatory muscle pain (Herb, Cho & Stiles, 2006). Myofascial pain and dysfunction of the masticatory muscles are more often stimulated by stress-related para-functional habits (i.e., clenching and grinding) (Herb et al., 2006).

TMJ pain from an articular disorder may conversely lead to myofascial pain (Herb et al., 2006). This is thought to happen due to reflex muscle contractions during mastication (Costa, Campos, Franca & D'Abreu, 2011; Okeson, 1985). Patients present with tenderness and hyperalgesia at sites distant from the joint, which may also include various trigger points (Herb et al., 2006; Murray & Peck, 2007).

It is known that any surgical incision in the masticatory muscles can affect their integrity, which, in turn, directly affects their function (Costa et al., 2014). Masticatory and cervical muscle disorders may result in changes in the mastication pattern, increasing the efforts of masticatory muscles, which may be followed by painful complications that could severely compromise the patient's quality of life (Costa et al., 2014; Figueiredo et al., 2006; Rocha-Filho, Fajarra, Gherpelli, Rabello & de Siqueira, 2007; Yasuda et al., 2010). Therefore, the dissection of masticatory muscles may cause cosmetic and functional problems in the patients (de Andrade Junior, de Andrade, de Araujo Filho & Carcagnolo Filho, 1998; Rocha-Filho et al., 2007; Yasuda et al., 2010).

A wide variety of brain pathology may require surgical intervention, with craniotomy being the most commonly used surgical access approach. Patients who undergo craniotomy to treat intracranial pathologies may suffer a severe limitation regarding maximum mouth opening and develop different degrees of pain in the masticatory muscles and TMJ function (de Andrade Junior et al., 1998; Figueiredo et al., 2006; Rocha-Filho et al., 2007; Yasuda et al., 2010).

A closer look at these patients, especially with clinical analysis methods, reveals negative consequences because of injuries to temporal muscle resulting from the surgical approach, including muscle atrophy due to direct harm, ischemia, inadequate muscle tension, or muscle denervation (Abdulazim et al., 2012; Rocha-Filho et al., 2007; Yasuda et al., 2010). These post-operative side effects may arise after pterional and fronto-temporal craniotomy required in treatment procedures for refractory epilepsy, brain tumours or cerebral aneurysms (Yasuda et al., 2010).

Despite the increased awareness of the consequence of effective pain management following surgical procedures, an inadequate pain relief for post-craniotomy TMD still poses a significant clinical problem (Costa et al., 2014).

In this review, we focus on the primary research literature on the pathophysiology, diagnosis and treatment of post-craniotomy TMD for priority directions in reducing the associated complications.

PATHOPHYSIOLOGY

The pathological processes underlying the symptoms of post-craniotomy TMD involve the temporal muscle (Figueiredo et al., 2007) as its adequate function depends on proper innervation, vascularization, muscle tension and integrity of the muscle fibers. The functional integrity of the muscle requires a perfect innervation, an excellent vascular supply, muscle tension and inappropriate repair of the muscle at the site of original attachment (Kadri & Al-Mefty, 2004; Miyazawa, 1998; Oikawa, Mizuno, Muraoka & Kobayashi, 1996).

It is necessary an overview of the temporal muscle anatomy to better understand the pathophysiological data.

a) Muscle Components

The fan-shaped temporal muscle is composed of a central portion and three muscle bundles, namely, antero-medial, antero-lateral, and middle lateral (Kadri & Al-Mefty, 2004). The antero-medial muscle bundle is originated from the infra-temporal crest of the higher wing of the sphenoid bone, passing inferiorly and being inserted into the anterior region of the medial surface of the coronoid process and temporal crest. The antero-lateral muscle bundle is positioned on the lateral surface of the aponeurosis of the central part of the temporal muscle, and the cranio-medial region of this bundle is adjoined with the fleshy part of the temporal muscle. The middle lateral muscle bundle is observed as a thin sheet on the lateral surface of the temporal muscle aponeurosis in the middle region of its main part (Shimokawa, Akita, Soma & Sato, 1998).

b) Innervation

The anterior division of the mandibular nerve innervates the temporal muscle. This nerve frequently presents three branches: masseteric, middle deep temporal and buccal nerves. The anterior deep temporal nerve is a branch of the buccal nerve that can give rise to one or more branches. The buccal and anterior temporal nerves pass through the lateral pterygoid muscle, between the upper and lower heads of the muscle at its anterior aspect. Next, the anterior deep temporal nerve separates from the buccal nerve and divides into many tiny branches that supply the antero-lateral and antero-medial bundles, including the anterior part of the main portion of the temporal muscle (Kadri & Al-Mefty, 2004).

The middle and posterior deep temporal nerves run through the superior surface of the upper head of the lateral pterygoid muscle. The middle deep temporal nerve can originate separately or share a trunk with the masseteric nerve, which separates after leaving the foramen ovale, and innervates the middle part of the main portion of the temporal muscle and

the middle lateral bundle. The posterior deep temporal nerve originates from the masseteric nerve as one or many tiny branches before it reaches the superior border of the upper head of the lateral pterygoid muscle, turning downwards to innervate the masseter muscle. The posterior deep temporal nerve supplies the posterior part of the main portion of the temporal muscle, with the masseteric and deep temporal nerves being related to the dorsal root of the zygoma (Kadri & Al-Mefty, 2004).

c) Vascular Components

In men, the blood supply to the temporal muscle is mainly derived from the anterior and posterior deep temporal arteries. There is an extra blood supply originating from the middle temporal artery, a branch of the superficial temporal artery (Cheung, 1996).

Effects of the Surgery on the Temporal Muscle

Alteration of the temporal muscle during neurosurgical procedures often results in tissue trauma, including fibre atrophy, presence of fibrotic tissue within the muscle, and reduction in muscle strength (Costa et al., 2014; de Andrade Junior et al., 1998; Rocha-Filho et al., 2007). Other abnormalities include cosmetic deformities (anterior temporal hollow) and functional handicaps (Kadri & Al-Mefty, 2004; Park et al., 2015). The post-operative sequelae of the temporal muscle may be originated from the following factors:

Consequences of Denervation

The return of motor function of a denervated muscle depends not only on the restoration of nerve supply, but also on the capacity of the muscle to respond (Wang, Gu, Xu, Shen & Li, 2001). After denervation, the skeletal muscle undergoes a sequence of morphological, physiological, biochemical, functional, and metabolic changes (Kadri & Al-Mefty, 2004; Wang et al., 2001). With prolonged denervation, the blood supply deteriorates and fibrosis progresses with ultimate replacement of muscle by fat tissue. All three deep temporal nerves are positioned superficially to the sub-periosteum and may be injured by dissection of the soft tissue. Therefore, sub-periosteal dissection is of vital importance in preserving the nerves (Kadri & Al-Mefty, 2004).

Consequences of Devascularisation

Muscular ischemia due to prolonged retraction or interruption of blood supply can produce irreversible damage after micro-vascular occlusion caused by propagation of thrombus, causing fibrosis and atrophy (Kadri & Al-Mefty, 2004; Miyazawa, 1998).

Integrity of the Fibres and Muscle Tension

Muscle tension is critical in conserving functionality and preventing atrophy from disuse (Kadri & Al-Mefty, 2004; Zager, DelVecchio & Bartlett, 1993) as muscular attachments should be preserved to maintain the contraction of the muscle. Nevertheless, the injured fibres become fibrotic and present scars, thus harming the vascular and nerve supply to the distal part of the flap, which increases atrophy and asymmetry after surgery (Kadri & Al-Mefty, 2004). Preservation of the muscle fibres and restoration of the muscle alignment as similar as

possible to that prior to surgery is crucial to minimise post-operative deformities of the muscle (Park et al., 2015).

Post-Craniotomy TMD

It has been shown that patients undergoing the same procedure for craniotomy may or may not develop muscle atrophy and/or TMD (Costa et al., 2014; de Andrade Junior et al., 1998). Dissection of the temporal muscle has an immediate effect, generating hypomobility caused by weakness and retraction of the TMJ muscles (Park et al., 2015). These factors can induce degenerative or adaptive changes in the joint tissue (Costa et al., 2014).

TMJ is often and intensively affected in patients who underwent craniotomy (Costa et al., 2014; de Andrade Junior et al., 1998; Rocha-Filho et al., 2007; Yasuda et al., 2010). It is interesting to note that the degree of joint impairment differs among these patients.

In post-craniotomy patients, many factors such as masticatory muscle weakness, dental malocclusions and bruxism can affect the dynamic balance or equilibrium between the components of the masticatory system (Costa et al., 2014). Bruxism is a non-painful disorder characterised as a repetitive jaw-muscle activity, such as clenching or grinding of the teeth and/or bracing or thrusting of the mandible (Lobbezoo et al., 2013).

Bruxism with undesirable occlusal patterns may lead to damage to joint tissues at molecular level, thus predisposing to joint intra-capsular dysfunction, joint effusion and pain (Costa et al., 2014).

In general, TMD can be influenced by concurrent myofascial pain and/or bruxism. Moreover, degenerative lesions in muscle fibers and inflammation after craniotomy can compromise the normal joint biomechanics, producing deleterious effects or degenerative changes in the TMJ (Costa et al., 2014).

DIAGNOSIS

The presence of concomitant bruxism is considered a risk factor for post-craniotomy TMD that can affect the surgical outcomes, being recognised as a causal agent involved in its initiation and/or perpetuation (Costa et al., 2014). Therefore, it is important that the physician determines the diagnosis of TMJ before surgery.

The diagnosis is clinical and uncomplicated, with evaluation being based on the patient's information, history and clinical analysis of TMJ. A TMD specialist can provide a global vision of the joint and mastication muscles by searching for pain/tenderness on palpation, joint noises, jaw function limitation, masticatory muscle pain, para-function habits (e.g., clenching, bruxism, nail biting) and anomalies of occlusal functions (Ahmad & Schiffman, 2016).

TREATMENT

Patients always present pain and mouth opening limitation during the first post-operative months (Yasuda et al., 2010), with the individuals showing gradual improvement over time.

However, in some patients, symptoms may persist by reaching the joint and affecting structures (disc or cartilage) in the TMJ (Costa et al., 2014; Kadri & Al-Mefty, 2004).

Because the clinical presentation of post-craniotomy TMD is heterogeneous, the treatment should be individualised for each patient depending on pain severity, comorbidities, and level of functional impairment.

The management includes physical therapy to re-establish the mandibular function as soon as possible, with manual therapies (e.g., jaw exercises and re-education) being shown to be effective to reduce pain and recover mobility/function in the patients (Melis, 2013).

Manual therapy using soft tissue techniques, mobilisation, exercises and manipulation is proposed to reduce local ischemia, stimulate proprioception, break fibrous adhesions, generate synovial fluid production and reduce pain (Kalamir, Bonello, Graham, Vitiello & Pollard, 2012).

Active and passive range of motion exercises target to re-establish physiological movements by means of opening, laterotrusion, protrusion and retrusion movements have been shown to significantly reduce pain and injury, in addition to increasing the range of motion (Kalamir et al., 2012; Michelotti, Parisini, Farella, Cimino & Martina, 2000).

ABSTRACT

Bronchoscopy has become an important procedure, which is performed for diagnostic and therapeutic purposes. There has been very important expansion in the application of bronchoscopy due to technological developments. Bronchoscopic techniques have acquired use as diagnostic procedures in the context of infection or malignancy. Over recent years, procedures such as endobronchial ultrasound have become widely used. Similarly, new technologies such as navigational bronchoscopy are becoming more commonly used. In addition, bronchoscopy has extended its application into interventional procedures. For example, in the context of Chronic Obstructive Pulmonary Disease, bronchoscopic insertion of endobronchial valves has become widely used. Bronchoscopy also can be used for photodynamic therapy in the context of lung cancer. In this chapter the medical and surgical advances in bronchoscopy will be described.

Keywords: bronchoscopy, endobronchial valves, endobronchial ultrasound, photodynamic therapy

INTRODUCTION

Bronchoscopy has become an important procedure, which is performed for diagnostic and therapeutic purposes. It is a common procedure with over 500,000 bronchoscopies being performed in the USA each year (Ernst, Silvestri, and Johnstone 2003, Silvestri et al. 2012). Due to technological developments, as well as improvements in imaging bronchoscopy, techniques have become more complex. The first bronchoscopy was performed by Gustav Killian in 1897 to remove a foreign body from the patient's main bronchus (Batra and Yarmus 2018). Subsequently, the rigid bronchoscope became an important tool for examination of the proximal bronchi. The main limitations of rigid bronchoscopy include the requirements for general anaesthesia and the fact that it only allows visualization of the carina and main bronchi (Annigeri and Patil 2017). In 1967 Shigeto Ikeda introduced flexible bronchoscopy, which allowed for visualization beyond the main bronchi. Flexible bronchoscopy has other advantages compared with rigid bronchoscopy. The procedure is performed under an awake sedation, seldom requiring general anaesthesia. The technique is easier to master, compared to rigid bronchoscopy, which may be technically more difficult. Over recent years, due to technological developments, there have been new techniques introduced such as auto-fluorescence bronchoscopy, endobronchial ultrasound, electromagnetic navigational bronchoscopy, photodynamic therapy bronchoscopy and endobronchial valves (Mehta et al. 2018)

FLEXIBLE FIBREOPTIC BRONCHOSCOPY

Flexible fibreoptic bronchoscopes have glass fibres, which allow for light to be transported from the light source to the distal part of the scope, delivering images from the end of the scope to a high definition screen (Du Rand et al. 2013). The flexible fibreoptic bronchoscope has instrumentation and suctioning channels, therefore it allows for both the examination of the bronchial tree and introduction of instruments such as bronchial brushes or bronchial biopsy forceps. Therapeutic scopes have a larger instrument channel allowing for the introduction of instruments which can be used for diagnostic and therapeutic purposes (Du Rand et al. 2011).

Fiberoptic bronchoscopy is usually undertaken in the endoscopy suite or operating theatre, supported by staff capable of preparing the equipment, managing the collected samples and caring for sedated patients. The operator needs to be skilled in the administration of awake sedation, potential indications or contraindications and complications of the procedure, as well as having extensive knowledge of bronchial anatomy and pathology (Wahidi et al. 2011). The learning of bronchoscopy skills is a complex process (Rayl, Pittman, and Shuster 1988, Silvestri et al. 2012). However, the historical apprenticeship type of learning of bronchoscopy skills is gradually changing with the wider application of simulation technology (Kvale and Mehta 2001, Silvestri 2008). This approach, based on simulation training of the procedural skills in the laboratory, reduces the stress of the learning of complex procedures, when compared to learning in clinical settings; it can be used in conjunction with lectures or web based teaching (Blum, Powers, and Sundaresan 2004, Davoudi and Colt 2009, Haponik et al. 2000, Torrington 2000).

Fiberoptic bronchoscopy can incorporate auto-fluorescence, which has higher sensitivity to detect early or precancerous changes, though it is mainly used for diagnostic purposes. Therefore, procedures such as bronchial washing, bronchial brushing and bronchial or trans-bronchial biopsies are the most common procedures undertaken during bronchoscopy (Du Rand et al. 2013). One of the other important aspects of fiberoptic bronchoscopy includes bronchial secretion clearance, which may be of particular use in patients on mechanical ventilation. From the diagnostic aspect, perhaps the most common application of fiberoptic bronchoscopy is in the diagnosis of lung cancer. This is of particular importance in patients with visible endobronchial tumours which can be biopsied during the procedure; additionally, it can be used pre operatively to plan surgery. Moreover, fiberoptic bronchoscopy performed by a skilled operator can be used for retrieval of a foreign body, although a rigid bronchoscopy may be more appropriate (Du Rand et al. 2011). The rigid bronchoscope may allow better access for the removal of the foreign body, controlling of bleeding, ability to introduce larger instruments and, as it is performed under general anaesthesia, better oxygenation control as well as more appropriate access to interventional procedures if required.

PHOTODYNAMIC THERAPY

Photodynamic therapy (PDT) is a treatment which comprises of a chemical photosensitizer, a matching wavelength of light, usually generated by laser, and oxygen, which is present in all living tissues. The interaction between light and photosensitizer, in the presence of oxygen, generates singlet oxygen and other cytotoxic species leading to cell death (Allison and Moghissi 2013). For central lung cancer PDT is carried out bronchoscopically, as a two-step procedure (Moghissi and Dixon 2008, 2003, Okunaka and Kato 2002, Ikeda et al. 2011). The first step, pre-sensitization, involves intravenous administration of photosensitizer, which is distributed throughout the body; a higher concentration will be retained within the cancer compared with normal, surrounding tissues. The second step is illumination, during which the pre-sensitized cancer tissue in the airway is exposed to an appropriate laser light transmitted via an optical fiber, which is passed through the bronchoscope. The cancer tissue containing photosensitizer, in the presence of oxygen, is activated by the laser light, prompting destruction of cancerous tissue. The pre-requisite for bronchoscopic PDT is the presence of an endo-luminal, biopsy proven, malignant tumour in the airway, following standard investigations and staging procedures. Standard treatment for malignant broncho-pulmonary tumours consists of surgery, radiotherapy and chemotherapy. However, a number of other “non-standard” options have recently become available, all of which are basically local therapies. PDT is one such option with a number of important attributes. PDT is the only method amongst non-standard therapies, which specifically targets cancer with the exclusion of healthy surrounding tissue.

Bronchoscopic PDT in lung cancer can be used in the context of an early stage central endobronchial cancer with the aim of ‘curative intent’ (Ikeda et al. 2011, Moghissi et al. 2007). Also, PDT can be considered in locally advanced inoperable endobronchial cancer (Moghissi et al. 2007, Okunaka and Kato 2002). Here, the aim is to open up a lobar or main stem bronchus, which is blocked by cancer, thus allowing pulmonary ventilation. There is an

increasing tendency to use PDT in such cases within a multi modal protocol (Ikeda et al. 2011). Another application of PDT is in metachronous, endobronchial tumours of the residual lung after previous resection for local bronchial stump recurrence as an induction therapy prior to surgery and for rare bronchial tumours, such as carcinoid and adenoid cystic carcinoma (Moghissi et al. 2007, Moghissi and Dixon 2003, Ross et al. 2006, Akopov et al. 2017, Moghissi and Dixon 2017). However, in practice all cases fall within endobronchial malignancies confined to bronchial mucosa with no parenchymal lesion and without nodal or distant metastases. PDT can be offered with curative intent for locally advanced cancers, which are bulky endobronchial tumours with no distant metastases but with atelectasis. In these, PDT offers palliation with survival benefit in some.

Prior to bronchoscopic PDT, an informed consent should include information on photosensitivity skin reaction to direct or indirect sunlight exposure. Bronchoscopic assessment should aim to delineate the extent and topography of tumour using white light and auto fluorescence bronchoscopy. Currently, Photofrin (Porfimer Sodium) is the photosensitizer of choice. The interval between drug administration and treatment allows wide distribution in the body and retention predominantly in cancer tissues. There are two methods available for illumination. During the first method, which is performed under general anesthesia, the rigid bronchoscope is initially inserted, through which the flexible fiberoptic bronchoscope is subsequently introduced. Exposure to light of the pre-sensitized tissue is undertaken via an optical fiber; this is passed through the biopsy channel of the flexible fiberoptic bronchoscope. The second method uses a flexible fiberoptic bronchoscope under awake sedation and local anesthesia. The optical fiber is passed through the biopsy channel of the flexible fiberoptic bronchoscope, directing the laser light to the target. Bronchoscopic PDT under general anaesthesia is the preferred method, except when this is not possible or rejected by the patient, as it allows for better airway protection, reduces coughing and improves patient comfort. Current literature suggests that PDT in the context of an early lung cancer may achieve long survival in between 60 -70% of cases (Ikeda et al. 2011, Okunaka and Kato 2002). In locally advanced cases PDT offers good palliation with improved pulmonary function and survival benefit in some cases (Moghissi et al. 2007, Moghissi et al. 1999). It is relevant to point out that PDT can be used with standard treatments, notably chemo-radiation; it is a treatment, which can be repeated. The only problem can be photosensitivity skin reaction over a variable duration, according to the photosensitizer employed, hence the need for effective patient counseling.

ENDOBONCHIAL VALVES

Patients with Chronic Obstructive Pulmonary Disease (COPD) have increased lung compliance and airway resistance, due to small airway obstruction leading to air trapping, resulting in the increase in total lung capacity (TLC) and residual volume (RV) leading to hyperinflation (Herth et al. 2016). During exercise the respiratory rate is increased which, in turn, leads to a shorter time for lung emptying; this, in turn, increases end expiratory lung volume and produces dynamic hyperinflation, thus leading to increased work in breathing and symptoms of breathlessness. Lung volume reduction surgery seems to affect those changes, probably through a combination of improvement of lung recoil, changes in lung size and its

effects on respiratory muscles. Lung volume reduction surgery involves resection of emphysematous lung with the aim of reducing lung volume. In recent years non-surgical procedures, in the form of endobronchial valve insertion, have become more widely used. The Valve for Emphysema Palliation Trial (VENT) compared endobronchial valve placement with best medical therapy (Sciurba et al. 2010). The endobronchial valves were placed unilaterally in the lobes that had the worst emphysema. Results showed that at 6 months there was significant increase of FEV₁ by 60 ml and the 6 minutes walk by 19.1 meters (5.8%) in the endobronchial valve group compared with the medical treatment group. The other important finding of the VENT study was that patients with intra-lobe heterogeneous emphysema of more than 15% and the presence of complete fissures had the best improvements in FEV₁ and the 6 minute walk. The IMPACT study showed that patients with homogenous emphysema and who had no collateral ventilation in the targeted lobes can also benefit from endobronchial valve treatment (Valipour et al. 2016). The benefits observed were related to improvements in the FEV₁, 6 minutes walk and quality of life. Similarly, the STELVIO study showed significant improvement in patients with emphysema who had endobronchial valve insertion compared with the control group at 6 months in mean FEV₁ measurements by 178% and mean 6 minutes walk distance by 23.3% (Hartman et al. 2018, Klooster, Hartman, et al. 2017). In the LIBERATE study, endobronchial valves were evaluated in patients with heterogeneous emphysema and little or no collateral ventilation in the target lobe, showing improvement in lung function, exercise tolerance and St George's Respiratory Questionnaire scores (Criner et al. 2018). In the endobronchial valve group the improvements in FEV₁ were 0.106 L ($p < 0.001$), 6 minutes walk of 39.31 meters ($p = 0.002$) and for St George's Respiratory Questionnaire Score reduction by 7.05 points ($p = 0.004$). Pneumothorax was observed in 26% of cases.

Endoscopic lung volume reduction can be performed using a flexible bronchoscope. This form of treatment can be used for patients with severe COPD who have been carefully assessed. The currently accepted criteria for endoscopic lung volume reduction include FEV₁ ranging from 15% to 50% of predicted and residual volume of more than 175% of predicted (Herth et al. 2017). Patients should be advised to stop smoking, their medication should be maximized and they should have been through a pulmonary rehabilitation process. In addition, the patients should be stable prior to procedure and should be able to undergo general anesthesia or awake sedation. Radiological imaging should exclude other pathologies and provide evidence of the presence of complete fissures. In some cases, imaging may not be able to definitively confirm the absence of collateral ventilation in the lobes targeted for endobronchial valve insertion, even using more advanced imaging technology. For this reason the most accepted method for precisely assessing collateral ventilation status is the Chartis Diagnostic System (Pulmonx) (Slebos et al. 2017). The procedure of endoscopic valve insertion and the Chartis measurements are recommended to be performed under general anesthesia as this allows for better airway management. There are recommended settings of ventilation, such as low ventilation frequency and long expiratory settings as, these are less likely to affect the Chartis measurements (Slebos et al. 2017). During the Chartis procedure, patients require adequate levels of sedation whilst still being able to produce tidal breathing for negative collateral ventilation to be detected. However, because the patients have advanced COPD, during the procedure they need to be monitored for respiratory failure and carbon dioxide retention. Therefore, sedation used needs to be easily reversible; most commonly, agents used are short acting benzodiazepines and opiates. Similarly, good

secretion management is of importance. The use of positive pressure ventilation is recommended for both the Chartis measurements and the placement of the valves. Although the procedure can be performed under awake sedation there are clear advantages of general anesthesia and positive pressure ventilation (Slebos et al. 2017, Shah et al. 2017). The patient is more comfortable; coughing and the management of secretions may be easier. In fact, if Chartis assessment is inconclusive under awake sedation, measurements may be improved when performed under general anaesthesia, especially in patients who have fissure completeness above 80%. In addition, it is recommended that Chartis measurements and the placement of valves is undertaken at the same time, thus reducing the risks of COPD exacerbation due to repeat bronchoscopies if procedures were performed separately.

The decision where to place the endobronchial valve is determined by imaging that locates the distribution of disease and characterizes fissures, as well as findings of the Chartis measurements. Imaging characteristics of the targeted lobes should include assessment for the presence of fissures, absence of collateral ventilation, presence of emphysema and low perfusion on perfusion scintigraphy (Slebos and Shah 2016, Koegelenberg et al. 2015, Herth et al. 2016). Valve placement also needs to take into consideration careful assessment of the bronchial anatomy. This should consider the size of the bronchi as well as their proximity, since this determines the order of the valve placement. It is normal practice to first place valves in the more distal bronchi to avoid valve overlap, which may prevent placement of subsequent valves into the more distal segments. The depth marker on the endobronchial delivery catheter allows assessment of the distance of valve protrusion post placement.

The most common complications of insertion of endobronchial valve include pneumothorax, infection and misplacement of the valve (Herth et al. 2017, Slebos et al. 2017). These complications require rapid intervention, such as treatment of infection; this would usually involve nebulised bronchodilators, systemic corticosteroids and antibiotics. Pneumothorax has been reported to occur in around 20 to 30% of cases (Klooster et al. 2015, Klooster, Slebos, et al. 2017). The majority, around 80% of cases of pneumothorax, occur in the first 2 days post procedure, with one in ten occurring after 6 days and around 10% between day 3 and 5 post procedure (Skowasch et al. 2016). The management of pneumothorax should follow international guidelines and involve rapid chest drain insertion to avoid tension pneumothorax (MacDuff, Arnold, and Harvey 2010). There are currently two endobronchial valve systems: Zephyr that has been more widely used and Spiration endobronchial valve. There are other options such as self-acting coils, use of biodegradable sclerosant or thermal vapour.

ENDOBRONCHIAL ULTRASOUND

Mediastinoscopy is the gold standard for mediastinal lymph node staging in the context of lung cancer. Imaging, such as computed tomography (CT), Positron Emission Tomography (PET) or Magnetic Resonance Imaging (MRI) in some cases, provide non-invasive methods for mediastinal lymph node staging (Whitson et al. 2013, Rintoul et al. 2009). Other options for staging mediastinal lymph nodes include Endobronchial Ultrasound (EBUS), Endoscopic Ultrasound (EUS) or blind Trans-Bronchial Fine Needle Aspiration (TBFNA) sampling. CT and PET can identify mediastinal lymph node involvement in NSCLC with sensitivity of 60%

to 85%, specificity of 84% to 94% and accuracy of 78% to 96% (Groth and Andrade 2008). Cervical mediastinoscopy has sensitivity of 86% to 93% and diagnostic accuracy of 93% to 96% (Annema et al. 2010, Yasufuku et al. 2011). It has been reported to have morbidity of 0.6% to 1.1% (Hammoud et al. 1999). EBUS is a less invasive procedure compared with cervical mediastinoscopy and can be performed under awake sedation as well as under general anaesthesia.

Accurate staging of lung cancer is important for prognostic and therapeutic reasons. EBUS was introduced in the early 1990's. The early technology introduced a radial probe, which allowed for visualization of the airway wall with close proximity to the exterior of the airways (Herth, Becker, and Ernst 2003). With improvement, it allowed for the use of a radial probe with a flexible catheter and a balloon to perform biopsies, including transbronchial needle aspiration but not real time procedures. Convex probe development resulted in the ability to perform real time visualization of the lymph nodes with real time ability to biopsy lymph nodes. EBUS, using a convex probe allows for lymph node staging and biopsy, diagnosis of mediastinal tumours and diagnosis of lymph nodes of unknown aetiology, for example in the context of undiagnosed TB or sarcoid, or biopsy of a pulmonary neoplasm (Gompelmann, Eberhardt, and Herth 2012, Herth and Eberhardt 2007). The EBUS convex probe is a 7.5 MHz transducer, placed at the tip of the scope; it is a linear, curved array scanning parallel to the scope insertion. The images are produced by directly contacting the probe with the bronchial wall, or they can be enhanced by attaching a balloon to the end of the scope. The scope also allows for visualization of the bronchial tree with conventional flexible bronchoscopy imaging. EBUS can also use Doppler mode to identify blood vessels. Radial probe EBUS can be used to assess the airway wall and its layers and to localize lymph nodes close to the trachea and bronchi, thus allowing subsequent lymph node biopsies, though not under real time ultrasound guidance, to localize lung lesions and subsequently guide placement of a guide sheath for biopsy. EBUS allows for a 22-gauge needle to be inserted through the working channel allowing for real time ultrasound guided transbronchial needle aspiration.

EBUS can be performed under general anaesthesia with an 8.5 mm or larger endotracheal tube as EBUS is slightly larger than a conventional fiberoptic bronchoscope. The endotracheal tube should be placed just below the glottis to allow for good apposition against the tracheal wall to provide good quality of images. This is of particular importance when sampling station 2 lymph nodes. The advantages of general anaesthesia include better control of oxygenation, improved sampling of smaller lymph nodes - less than 10 mm in diameter - by using intermittent apnoea, thus reducing patients' movement. The main disadvantages include the possible side effects of the anaesthetic agents, including hypotension and nausea, trauma from intubation and a longer recovery time. There was no difference in outcomes of EBUS performed under general anaesthesia compared with EBUS performed under conscious sedation, with reported sensitivity of 94.8% and 94% and 94% accuracy of EBUS performed under GA and conscious sedation respectively (Gompelmann, Eberhardt, and Herth 2012, Herth and Eberhardt 2007). Numerous studies have reported EBUS and EUS as relatively safe procedures with reported serious complications ranging between 0.05% to 1.43% (von Bartheld, van Breda, and Annema 2014). The most commonly reported complications, which are relatively minor, include cough, low oxygen levels that improve post procedure and, occasionally, high temperature which is self-limiting or may require antibiotic therapy.

EBUS can access American Thoracic Society (ATS) stations 2, 3, 4, 7, 10, 11; mediastinoscopy can sample stations 1, 2, 3, 4, 7 and EUS stations 2L, 4L, 7, 8, 9 (Groth and Andrade 2008). Using a fiberoptic bronchoscope mediastinal lymph nodes can be sampled but this is performed without direct visualization and was, not surprisingly, reported to have a wide diagnostic yield ranging between 40 to 75% (Groth and Andrade 2008). This inconsistency in diagnostic yield is the main disadvantage of the TBFNA. In a randomized controlled study EBUS diagnostic yield was 80%, which was statistically significant higher compared with that of TBFNA of 71% ($p < 0.005$) (Herth, Becker, and Ernst 2004). The use of the linear probe allows for real time procedure, with EBUS reported sensitivity of 89% to 99% and a diagnostic yield of 85% to 99% (Herth, Eberhardt, et al. 2006, Herth, Ernst, et al. 2006). Dong et al performed a meta-analysis, which pooled results from 1066 patients who had both EBUS and surgical analysis of the lymph nodes, revealing sensitivity of 0.90 (CI 0.84 to 0.96) (Dong et al. 2013). The findings were not greatly dissimilar to the earlier meta-analysis (Gu et al. 2009). Yasufuku et al, in a randomized controlled study which analyzed EBUS and mediastinoscopy for assessment of nodal staging, showed that both procedures had similar diagnostic accuracy of 93%, with no difference in sensitivity and negative predictive values (Yasufuku et al. 2011). In contrast, Um et al reported, in a prospective study of 127 patients who had both EBUS and mediastinoscopy, a significantly higher 93% accuracy for EBUS compared with that of 89% for mediastinoscopy (Um et al. 2015). However, Annema et al in a randomized controlled study, compared surgical staging with that performed with EBUS and EUS, showing that surgical sensitivity for detection of cancer was 79% and was similar to that of 85% for combined EBUS and EUS (Annema et al. 2010). The important finding of this study was that mediastinoscopy increased sensitivity by 9% if performed in cases where EBUS/EUS node sampling showed no evidence of cancer. In another study, Liberman et al prospectively assessed 166 patients already diagnosed or investigated for suspected lung cancer who underwent EBU/EUS and surgical mediastinal staging in the same setting and reported that EBUS had diagnostic accuracy of 91%, EUS of 88% and combined EBUS/EUS of 97% (Liberman et al. 2014). Therefore, based on currently available research EBUS has similar or slightly higher diagnostic yield when compared with mediastinoscopy. Moreover, combining EBUS with EUS may increase the diagnostic yield.

When performing EBUS, the planning of the procedure should be undertaken based on the most recent imaging, including CT and PET. It is good practice not only to review the images with respect to the lymph node characteristics and FDG uptake but also to compare radiological measurements of the lymph nodes with those of EBUS. Once the appropriate lymph nodes are visualized, a biopsy can be performed under real time. 10 to 15 needle passes are recommended and each lymph node should be sampled 1 to 3 times depending on the size of sample obtained (Gompelmann, Eberhardt, and Herth 2012). Many centers perform on site cytology analysis, which allows for decision whether the samples obtained are adequate to provide diagnosis; the decision can then be made whether additional sampling is required. Current practice is that samples should be sufficient for mutation testing, as systemic therapy requires analysis for EGFR, ALK and PD-L1. There are important issues related to the cytological analysis of the collected samples. The presence of lymphocytes can assist confirmation that the lymph node was sampled and is predictive of adequate sampling; the absence of lymphocytes has a negative predictive value for adequacy of sampling. There are potential issues of bronchial contamination that may result in false positive results. Sampling of the lymph nodes should be performed from more proximal to more distal e.g. N3

nodes followed by N2 nodes followed by N1 nodes as, otherwise, there is potential for contamination and upstaging of disease. EBUS can also be used for the diagnosis of sarcoidosis, TB or metastatic cancer from other sites. In cases of suspected TB, samples are required to be sent for histology and cytology, as well as microbiology and mycobacterial cultures. In some cases of chronic sarcoidosis where the nodes are fibrotic, a mediastinoscopy may be required for diagnosis. The role of EBUS in diagnosing lymphoma is not clear as diagnostic yield is variable; therefore, surgical biopsy may be more appropriate.

The learning curve for EBUS is variable even for the experienced bronchoscopists (Kemp et al. 2010). There is evidence that diagnostic yield of 90% can be achieved with around 50 procedures (Bellinger et al. 2014). Overall the learning curve depends on which node stations are sampled. For example, identification and sampling of stations significant in size, 7 subcarinal or para-tracheal 4R or 4L, would be much easier to master than small hilar nodes. In experienced hands even less than 5 mm nodes can be sampled. The American College of Chest Physicians (ACCP) recommends at least 50 procedures to establish proficiency in EBUS (Ernst, Silvestri, and Johnstone 2003). The ATS and European Respiratory Society (ERS) recommend at least 40 procedures under supervision (Bolliger et al. 2002). Others have observed that the learning curve was 10 procedures (Groth et al. 2008). The learning curve can be improved by the use of simulation training (Stather et al. 2012).

VIRTUAL BRONCHOSCOPIC NAVIGATION

Virtual bronchoscopic navigation, also called navigational bronchoscopy, involves the use of flexible bronchoscopy guided by virtual bronchoscopy to reach peripheral lung lesions (Asano, Eberhardt, and Herth 2014, Silvestri et al. 2012). Navigational bronchoscopy, when used with an ultra thin computed tomography, has been reported to have a diagnostic yield of between 65.4% to 81.6% (Asano, Eberhardt, and Herth 2014). When using an EBUS guided sheath, the diagnostic yield from the sampling of peripheral lesions has been reported at between 63.3% and 84.4%. The use of virtual bronchoscopy compared to the EBUS guided sheath improved the diagnostic yield. The navigational bronchoscopy has its advantages as, for an experienced bronchoscopist, there is very short learning curve which may not require additional training. The procedure is shorter compared to the EBUS guided sheath therefore associated with improved patient comfort with low complication rate, around 1% (Asano, Eberhardt, and Herth 2014). The main disadvantages are related to relatively high costs of the equipment which is the main limiting factor (Asano, Eberhardt, and Herth 2014, Silvestri et al. 2012).

CONCLUSION

In conclusion, due to technological improvements there have been interesting developments in the field of bronchoscopy. The use of new technologies has been applied in investigational procedures such as mediastinal nodes sampling using EBUS, thus reducing the need for mediastinoscopy. Moreover, navigational bronchoscopy may become more widely used for sampling of peripheral lung lesions. This new technique can be undertaken and easily learned by experienced bronchoscopists. Similarly, insertion of endobronchial valves

for patients with emphysema, or those with persistent air leak, are performed using flexible bronchoscopy. There is no doubt that, together with technological advances, new bronchoscopic techniques will be developed, widening the application of diagnostic and therapeutic bronchoscopic options.
